It will be well to constantly keep in view that we are strictly treating upon *portraiture*, as, of course, many of the conditions laid down would not equally apply to other branches of photography. To produce a portrait with any degree of truthfulness or artistic merit, it *must* be *natural*, but it does not follow that everything that is *natural* will necessarily be a *portrait*. Nature in *all* her aspects is not beautiful, but in making a portrait of her we should select such as will show her to the best advantage. We have all, no doubt, seen the instantaneous photographs of horses, showing them in the most absurd positions, devoid of all grace and beauty; surely if we were to paint a portrait of one we would not select such a position, notwithstanding that it was natural. No, we always select one where the animal looks to most advantage and shows its many *points* of beauty. As it would be with horses or animals generally, so it is with the human kind. There is a goodly amount of the ugly about us. We are naturally very beautiful, I will agree, but we could, if we tried, find some ugly *points* if we cared to bring them into prominence. Even if, in the reckless wish to be above all things natural, we were to select our ugliest and worst aspects, it would not add to the value of the picture as a portrait, but would considerably mar its claims to be considered a successful reproduction of nature.

Man, as an artist's model, is an ever-shifting subject, presenting an endless variety of ever-changing aspects of light and shade, most of which no artist could select for a portrait, and yet they are all most natural. To paint a successful portrait means much more than to simply secure on paper or canvas the copy of what is natural. Other elements have to be considered. Intellect and beauty must receive due attention at the artists' hands. Why is one operator more successful in the studio than another? Simply because he is endowed to a greater extent than his fellows with the power of securing grace and beauty in posing his subjects. It is undoubtedly natural that a person should wink, frown, or grin, or even occasionally loll or stretch himself, but who, with any judgment, would dream of selecting such actions as the leading characteristics of a portrait? These points apply not only to the artist about to paint a portrait, but also to the photographer about to take a sitter.

The aim of every true artist or artistic photographer is, therefore, to portray nature under such conditions and aspects as may best secure the intellectual character of the model, and invest same with a necessary amount of pleasing pictorial effect. In this the painter has a decided and very marked advantage over the photographer, and that advantage is *colour*. The eye of the observer can be led away from some defective or offensive spot by the influence and disposition of colour in a painting, while the photographer is hampered by having only one colour, if I may so call it, at his disposal.

The task before a painter or photographer desirous to obtain a successful *portrait* is anything but easy, and it speaks volumes for many operators the rapidity with which they despatch a sitter, and yet secure a characteristic and pleasing portrait. This fact will be more easily appreciated when it is remembered that Sir Thomas Lawrence and Sir Joshua Reynolds have repeatedly had as many as fifty sittings for a portrait. Now, if this be the case with two of our

most eminent painters, how must it be with the lesser lights. All this, too, in order to secure an expressive position or look best calculated to depict in the painting the character and disposition of the sitter. There is no one, I presume, who can think that all these sittings could be necessary for producing simply accurate drawings of models. Nowadays a great deal of this bother and worry to artist and model alike is obviated. Here photography helps us very considerably indeed. In less than an hour a number of plates can be exposed and afterwards developed, one of which will surely supply all our requirements, thus avoiding loss of time to all concerned, and in many cases serious expense to the sitter.

In the question of *expression* the painter has again the advantage. He may secure it in the course of an animated conversation, being able to allow the sitter every liberty. Thus he will catch the intellectual expression, which will give life to the picture and be the essence of the portrait. On the photographer's side is that death blow to expression, "Be still, please—I am going to expose!" The "look pleasant" so often expressed has seldom, if ever, a response on the part of the sitter. There is so much method about everything that the model is more likely than not to assume an expression quite foreign to him and so detract from the chances of his picture (no matter how good a photograph it may be) ever being a good and successful portrait.

The photographer who does not care to study the artistic bearings of portraiture is more likely to produce what may, not inaptly, be styled a map of the face. This, however, may be very far from being a portrait in the true sense. Retouching may or may not improve the state of affairs, depending upon the artistic training of the retoucher to whom the negatives may be given.

A happy accident, even in the hands of the most ignorant, I have known to achieve the most successful results; but, as I say, it was pure accident, and a similar result would never again be arrived at except by a recurrence of the accident. For this a photographer must not hope, and unless he studies and cultivates his artistic knowledge he can never hope to produce uniformly successful results. A photographer always finds it a great sorrow to give up his pet notion, that to succeed he has only to depict nature, reserving to himself the firm belief that a really good photograph is necessarily a faithful reproduction of the same as she is seen by the eye.

This, however, is a fallacy. In many cases the very best productions of the camera and lens, unaided by art, is anything but a truthful transcript of nature. The very principles of photography, chemical and optical, unite in rendering this inevitable. The photogenic action of the various colours, some possessing it to an extreme extent while others have it scarcely at all, from a chemical point, while the undue enlarging and diminishing of advancing and retiring objects, from a mechanical, combine to remove photography further from being a truthful reproducer of nature than many believe painting to be. Art will soften the peculiarities, if offensive, while photography very often will exaggerate them. The incipient wrinkle or insignificant scar, which in nature is scarcely observable owing to the brilliancy of the complexion, or the delicate freckle, which to the eye is lost in the general tint of the skin, form no defective points in the artist's portrait; but submit them to the cyclopean eye of the camera, and you will have them brought out in all offensiveness in the black and white of the photographer's photograph. Red or golden tresses, too, might just as well be black as the raven's wing for all photography cares. Give such a subject a blue eye, and where will be the balance and truth to nature of the photograph? In such cases is it that a photographer finds colour his only friend, and flies to him for help.

It is a principle in art, as regards portraiture, that all importance should be given to the head, the rest of the picture being quite subordinate. This, too, is true to nature, for how often will you see people and remember their faces, yet be quite unable to tell how they were dressed. Photography, however, knows not these delicate distinctions, every button, fold, and even the very texture of the material, is brought out with amazing distinctness. All this, in most cases, detracts very considerably from the prominence of the head, and often even reduces it to a mere detail.

In thus referring to the unavoidable defects in photography, I do not wish to depreciate photography, only to point out the advantages

in its artistic application. Let the photographer, like the colourist, study the works of the great masters in painting; what the latter gains in knowledge of colour the former will more than equal as regards position, disposition of drapery, light and shade. Portraiture produced under the best conditions of photography, guided by art, will not only be worthy of the best efforts of the colourist, but may even rival the best miniatures when skilfully finished.

REDMOND BARNETT.

(To be continued.)

FINISHING PHOTOGRAPHS.

Few will dispute that much of the beauty of the photograph depends on the manner in which it is finished. Finishing is here intended to be an inclusive term, applying to any and every means by which improvements can be effected in either negative or prints. The finest negative may be easily ruined by injudicious doctoring, or the most beautiful print rendered commonplace by the way it is either trimmed or mounted; so much depends on the final processes to which either one or the other is subjected. In the following remarks it is intended to glance at the various plans that have been adopted to improve our work, and, given a good negative, to get the best possible results from it. In the first place, the most careful attention must be given to the negative, whether portrait or landscape. To permit of a proper judgment it is absolutely necessary to take an impression before any alteration whatever is made prior to varnishing. In doing this, great care must be taken that both negative and paper are thoroughly dry, or a piece of talc may be interposed between the two if the weather happens to be moist, damp, and cold, or in all probability the film will become spotted with silver and much damaged, if not altogether ruined.

As good an impression as possible having been obtained, it is easy to determine what alteration can and may be made in the negative before it is put out for regular printing. In all probability some parts will be better for shading by the application of tracing paper or coloured varnish to the back of the negative in those places that print too dark. Some portions also will require reducing, either by rubbing down with spirit or scraping. Specks of white, or even unimportant small white objects, when they occur in a mass of shadow or darker portion of the negative, are better removed altogether by picking out with a needle or sharp knife point, such white specks being very detrimental to the masses of shadows, and far better removed from the negative at this stage than afterwards by colour on each print. Inequalities in the film may be now in a great measure remedied by the application of blacklead with a stump or finger's end over the too darkly printing portions. If the negatives are somewhat deficient in pluck the blacklead pencil will, by accentuating the high lights on buildings and prominent objects, wonderfully brighten it up, apparently increasing the scale of tone and depth of the shadows; in some cases a little water colour, judiciously applied, will be better than lead pencil, having rather more power of covering, but it must be used with discretion, too much being more objectionable than none at all, a white mark on a photograph being generally more conspicuous than a dark one.

The negative having been improved as much as possible by these means, it is better varnished, not only to protect the film but to prevent the improvements rubbing off; a line may be ruled round the negative with black varnish as a guide to laying on the paper in printing, and the name and number attached. The negative is now ready for the printer. The first few proofs should be examined to ascertain if the alterations made are right, and modifications made if required. Afterwards the finishing will be confined to the print itself, and the first thing to do is to decide on the shape—square, oval, or whatever may be thought to suit the subject best, the *shape* very much influencing the pictorial effect. To get at this it is advisable to have a number of masks of different forms to lay over a print, which is the best help to forming a judgment. One being selected, it must be slightly attached by gum at the corner to the negative to prevent shifting in printing.

The print on its removal from the press will have, or ought to have, a pure white margin, which is better slightly tinted down by covering the subject and exposing the margin a short time to

diffused light. Clouds, if required, must now be added; the print is then ready for toning and fixing.

With regard to vignetting, a favourite and decidedly artistic method of treating the print, there are several styles of doing it. The most usual is merely softening off the edges of the subject into the margin, and may be with a long graduation or more abrupt one. The abrupt style is very popular at the present time, and consists of nothing more than softening the edge of the masked prints to the extent of an eighth of an inch or so, a sort of intermediate style between the sharp edge and vignette proper; by this means a larger picture is secured than if the print has wide, graduated edges, but the delicate beauty of a good vignette is quite lost. This style is principally used for landscape. Another, and effective, method of vignetting is by sharply masking the upper portion and one side of the picture and softening off the rest—a plan now largely used in artistically illustrating books, and the effect is extremely pleasing; no better guide could be found than a careful examination of these engravings. Unfortunately, most landscapes require taking with special reference to this method of vignetting; an ordinary landscape, no matter how excellent for ordinary printing, will probably lack the framing, as it were, of branches and foliage that form so striking and effective a finish to the vignettes. The only available plan is to photograph a series of marginal foregrounds suitable, and combine them with the landscape by double printing—no very difficult task to any photographer of artistic instincts. To give a hint to those who have not tried the combination of double printing and vignetting, the course to be pursued is as follows:—Mask the landscape negative with the desired shape on the two or three sides, and vignette the unshielded side or sides in the ordinary way, the mask being slightly attached to the paper and removed with it. The negative of the marginal foreground, previously prepared by stopping out all the subject not required with black varnish, is held up to the light, the landscape, already printed and with mask attached, is adjusted upon it, carefully placed in the printing frame, and this again vignettied in the usual way. If it has all been properly managed the result is very charming. It need scarcely be said that artistic judgment must be brought to bear, and the result as a success or failure will entirely depend on the worker. This method of vignetting has not yet been much used, and opens up a field for picture making more novel than most, and, at the same time, is a good test of the photographer's artistic ability.

For ordinary vignetting, a toothed opening of a suitable shape cut in a sheet of blackened card or zinc and laid at a little distance over the printing frame, is about as good a plan as any. The vignetting glass abominations consisting of flashed orange glass, with the colour ground off to shape in the middle, do occasionally produce fair results, but generally give an egg-shaped or smooth-edged vignette anything but artistic. All vignetting should be either done in diffused light or under frames covered with white paper or ground-glass and printed in sunshine. For large pictures, a frame of card or wood laid over the printing frame, under the edges of which cotton wool has been tucked, is a favourite plan with some and excellent results are obtainable.

Portraits can be finished in several styles quite unsuitable for landscape. The vignetting may be effected in the same manner as for landscapes, or they may be vignettied into black backgrounds (a Russian plan that found some favour a few years ago), or they may be shaded, whilst the margin is tinted deep as the middle tints in the picture. Another plan is to print the portrait in an oval, then mask it and put a suitable landscape *very faintly* on the margin; a diaper pattern may be substituted for the landscape if preferred, but whatever it is the impression must be very light. Printing natural backgrounds to portraits is, I think, a specially artistic plan of treating photographs. A very few precautions are necessary to success. In the first place, the background must be rather light, shaded darker towards the bottom. The foreground must be regularly built up with rocks and plants, and which will, of course, be taken with the sitter. A print having been taken in the ordinary way, no masking being required, the light portions of the print are painted over thickly with gamboge and allowed to dry, when they are laid on suitable landscapes and printed. The colouring matter washes off without leaving any mark, and the shading of the background causes the whole to harmonise. The results, when properly done, are simply perfection.

Most small work is highly glazed either by burnishing or enamelling.

The effect in appearance is similar, but enamelled prints are much more permanent, if more trouble to make. An enamelled print may be rendered matt by rolling it through a press in contact with a finely grained surface. Whatever the pattern or grain on the plate it is reproduced on the enamel. Masks rendering the margins dull, or impressing a pattern without touching the portrait, is rather an effective method of finish. Embossing, in conjunction with this, has a good effect. For larger pictures, either portrait or landscape, cementing them to *colourless* glass with gelatine is a favourite method, as it certainly improves the looks of the photograph very greatly, but it is imperative to use only colourless glass, or a sickly greenish look is imparted, spoiling everything. The manner of mounting and the colour of the mounts have much influence on the photograph, also the decorations thereon frequently displayed. It is a moot question, from an artistic point of view, if the surroundings of a picture should be otherwise than quite plain. Many prefer a mount without even a simple line, the whole being treated as severely as possible, with the idea that anything that attracts attention in the slightest degree is detrimental to the picture. On a point where so many eminent authorities agree to differ, it may be fairly left to the photographer to use his own discretion. My own opinion is, that so long as the ornamentation is subdued and retiring, I see no objection to it in moderation. A plain line has the effect of binding the picture together; preferably it should be rather light in colour, certainly not black, and in many cases a marked improvement is the result. In pictures, where patches of light and shade end abruptly at the margin, with no connecting subject, a plainly mounted photograph looks bare and unfinished, a line round sets it right. The distance of the line from the print and the colour of it have considerable influence. Most photographs look best if a brown line is ruled about half or three-quarters of an inch from the subject.

Of all methods of mounting landscapes or large portraits, I give the preference to India paper laid down on white board, with a rather deep plate-mark, half an inch or so of the India paper showing at the margin of the print. This plan has a refined and finished appearance, and is suitable for all kinds of photographs. There are many other ways of finishing to which I have not alluded, inclusive of framing, which, to judge by the extraordinary and bizarre specimens we have of late years seen at our picture exhibitions, would indicate a very wide field for experiment. A safe rule for our guidance in this department is, that whatever the frame may be, let it be plain and good.

EDWARD DUNMORE.

HOW TO PREPARE GELATINE "POSITIVE" DRY PLATES.

ONLY about nine years have elapsed since gelatine dry plates displaced wet collodion for negatives, and great hopes were entertained, not only that gelatine would outlive collodion for negatives, but that the primitive dia-positive and ferrotype might be achieved by the modern dry plate process. And now it is admitted by competent authority that this anticipation has been realised, and with your permission I will briefly detail the course of experiments taken to achieve their successful preparation.

Some two years ago I had occasion to devote some time to laboratory chemical practice, and seeing some experiments made with hydrogen-peroxide on silver nitrate, I was induced to apply this agent to silver bromide, with the expectation of getting a white deposit on a gelatine plate, and to my satisfaction my anticipation was realised.

But of course much modification was needed to qualify the film for a proportionate deposit according to the varied intensity of the light. The simple application of the H_2O_2 either to the emulsion or developer did not suffice to bring about this desired effect.

From the appearance presented in the film, it occurred to me that the energy was too intense, though in the right direction, and I found that by diluting the hydrogen-peroxide with water, or allowing the bottle to stand uncorked, so that it lost part of its oxygen, the desired effect of relative deposit according to degree of intensity of light was effected. Much, however, had to be done to bring the process within the range of everyday practice, and it is only after a space of two years' intermittent experiment that a commercial value has been given to the gelatine glass positive and ferrotype.

For the sake of brevity we may dispense with detailing the original work for their preparation attempted two years ago, and proceed to give an account of the course taken to improve the uniformity of

the white film and increased rapidity in development. The great difficulty to be overcome was this uncertainty of whiteness, coupled with too much time occupied in development; the degree of whiteness depended essentially on the quantity of pyro used, and the less pyro used the longer development was required to get the result, which was much whiter than if more pyro were used. Without attending to this, nothing but a dull, leaden grey colour could be obtained, and this in a great degree prevented their commercial use, as was evidenced by the unsuccessful attempt to introduce them in America. Stimulated by seeing the agitation for them in America I thought it worth while attempting to improve them. The methods employed are, perhaps, worth recording here. Knowing as already stated that H_2O_2 alone would not suffice to give uniform whiteness without occupying too much time in development, it was necessary to find a means to accelerate development and preserve the tendency in the film to give a better white, and I found the yellow tint predominant to be due in a great measure to lack of chemical energy and prolonged development. Anticipating that it was the film that needed humouring to suit the developer, I applied sodic sulphite in an infinitesimal quantity to the emulsion after washing, and in considerable quantity to the ammonia developer, also some hydrogen carbonate of sodium; these ingredients gave the desired effect. Many experiments, however, were tried before the effectual one was arrived at.

A considerable variety of the fixed alkalis having been tried, the weaker ones showing best the direction most hopeful of attaining the object in view, this is perhaps contrary to saying that more intense chemical action was needed to get better whiteness. My reason for supposing this is supported by experiments made with different strengths of developers, also different degrees of emulsification. It was found that weak ammonia solution gave a greenish white when emulsification was carried to the maximum, and if sodic sulphite carbonate or bicarbonate were used nothing but a bright green could be got. Probably the colour is not attributable to intensity of chemical energy, but rather to the tendency of the different reducing agents to give a different isomeric character to the reduced molecule, which no doubt determines the colour. This must be taken as an amendment or limitation to the principle enunciated above, that the desired result was due to the intensity of chemical energy.

Whatever theory one may invent for a groove to practise in, ample scope should be allowed for error, because often preconceived notions are altered by a mere detail. For example, we see that practice shows that a strong developer was not the giver of the best white, but rather the mixed effects of ammonia and the weaker fixed alkalis combined with a modified emulsion. However, we see from this that the result has been arrived at not by rule of thumb but by noting the chemical actions of different reducing agents tending to give a white film. And in conclusion of this paper, intending to convey an idea of the methods pursued in finding the new departure, it may be worth adding that at last I have found that one of the ingredients can be dispensed with, and with the advantage of giving a uniformly better white; in fact, if the developer be properly regulated only a very slight change from an ordinary emulsion is needed. And in continuation of this paper I propose to give the formula and methods of preparation and manipulation. The tintype and dia-positive business is at present but little practised, but let us hope that at no remote date an agitation for this now minor adjunct in photography may crop up. Were such a time coming, a demand for dry ferro or glass positive dry plates must ensue. Therefore an excuse for occupying your valuable space by such a minor contribution may be acceptable, on the ground that the recording of such experience may be of service to those it may concern at a future time.

JOSEPH GRAY.

PHOTOGRAPHIC INDUSTRIES.

McKELLEN'S CAMERA FACTORY.

THAT Manchester has exercised a powerful influence on the engineering of the world, especially as regards precision of measuring appliances, is well known and fully recognised by every mechanic; and that it is exercising a potent influence on the cameras, more especially those of the portable class of landscape instruments, is now being equally well known to photographers.

The latest addition to the editorial collection of cameras of this class, and one which is greatly prized on account of its compactness, lightness, rigidity, and excellent fitting and finish throughout, being one which emanated from a maker whom we, rightly or wrongly, regard as the founder of the modern Manchester school of cameras, Mr. S. D. McKellen, we took advantage of a hurried visit to the great Cotton Metropolis Jubilee Exhibition to pay an equally hurried visit to the McKellen camera factory.

Having graduated in a watchmaking school—perhaps of all

mechanical institutes that which evokes the mechanical and inventive faculty more highly than any others—small thanks to Mr. McKellen that he is not only ingenious in conception but is able to carry his conceptions into practical execution. What we are glad of, however, is this, that being a photographer he has allowed the black art to influence his inventive and constructive faculties to an extent which renders photographers the gainers. With perhaps pardonable pride he can point to the fact that the only medal ever awarded hitherto by the Photographic Society of Great Britain for cameras was given to him, and we suppose he must feel it as a compliment that others in this line of business are imitating him as closely as the patent laws will permit.

There is no need for us here to descant on the characteristics of the McKellen camera, as these are already well known to our readers, either by description in these pages or by practical acquaintance with the article itself. What we purpose speaking about is the place, as we witnessed it in operation, where the McKellen cameras and other apparatus are made.

The factory is situated in a street within a mile or so of the office or sale room in Spring-gardens, near the centre of Manchester, if the huge city can be said to have any centre. It is composed of two buildings connected with each other by means of a gangway, which passes over a lumber yard beneath, the large entrance gate to which bears the name and purpose of the factory within in terms so large and emblazoned that he "who runs may read." In the timber store department we saw many samples of choice mahogany so thoroughly dry, so far as we could judge, that one may have conceived them to have done duty as bedsteads or other domestic appliances since the times of Queen Elizabeth. Drying racks are also erected on the ground floor in proximity to a gas engine which drives the machinery of the factory.

One room is devoted to the manufacture of dark slides and roller slides; another to the cameras themselves. We were shown thin morocco skins specially prepared for bellows bodies, these being for an outside covering of the more substantial opaque textile fabric which forms a substratum for this important part of the camera. In the McKellen camera and legs there are, exclusive of the ordinary wood screws, over one hundred pieces of brass, all made for their special purpose, and each one of which has to be fitted by hand. There must, therefore, always be a large amount of handwork in the camera.

Mr. McKellen, however, has in use a number of ingenious wood-working machines and cutters, all of his own designing, driven by a fine four-horse Otto gas engine; and with a view to a more rapid execution of his orders, which up to the present time have far exceeded the capacity of the works to keep pace with, he has made arrangements for further extension of the labour-saving principle. And amongst the most recent of the machines for that purpose we saw in operation elsewhere a planing machine—which is about to be transferred to the factory—which planes wood of every degree of thickness and with a degree of precision and smoothness so perfect as to leave the surface in a state requiring but little to fit it for the French polishers. A sandpapering machine, on the American principle, is also to be added to the factory appliances as a labour saver.

There are about thirty-five skilled workmen employed altogether, including workers in both brass and wood.

In his city office warehouse, Mr. McKellen has fitted up a very neat and commodious dark room, where clients and others may change or develop plates, or do any of the thousand and one things that a dark room is very useful for; and we are authorised to say that any photographer, whether a client of the firm or not, may make use of it at any time without charge.

PHOTO-MICROGRAPHS AND MICRO-PHOTOGRAPHS.

SOME time back Dr. R. L. Maddox asked me to hunt up the origin of the word "*Photo-micrograph*," and as I have succeeded in running it to earth I think it may be as well to place it on record.

In *The Photographer* (a manuscript photographic journal), conducted by J. Traill Taylor, printed in the then named *Liverpool and Manchester Photographic Journal* (now *THE BRITISH JOURNAL OF PHOTOGRAPHY*) for August 15, 1858, pages 203 and 414, also in Sutton's *Photographic Notes*, vol. iii., 1858, pages 205, 208.

Page 205, J. T. Taylor writes:—"By the way, will Mr. Shadbolt (who is an authority in microscopy) or any one else kindly suggest a suitable name for such magnified pictures? 'Micro-photograph' won't do, because that name has been given to the reduced pictures."

Page 208, George Shadbolt replies:—"The word micro-photograph originated, I believe, with myself, and is applied, I think, correctly to very small photographs, not to photographs of small objects, which would more correctly be 'photo-micrographs;' but probably a con-

venient word for this class of subjects, as well as for enlarged copies generally, would be mega-photograph."

The word "photo-micrography" is certainly a good test for a public speaker, and I have vivid recollections of struggles with it on my own and other persons behalf. I think, however, with Dr. Maddox, that custom has established it too firmly to permit of its replacement by something more harmonious and easy flowing. I should like, however, to call attention to Mr. Shadbolt's excellent word "mega-photograph;" it seems to me that this would be much better than the term "enlargement."

W. JEROME HARRISON.

WHERE TO GO WITH THE CAMERA

A TINY TOUR.

A $7\frac{1}{2} \times 5$ CAMERA; a 9×7 Steinheil lens; three double backs garrisoned with instantaneous plates; a focussing cloth; a tripod head; a camera screw. These comfortably filled a stout canvas case, which was furnished with a sufficient length of strap to admit of the whole being slung round the shoulders and shifted from side to side as occasion or convenience required. The stand was of the customary pattern, and portable enough to be grasped by the right hand *à l'alpenstock*, whilst the left firmly but affectionately held the peaceful calumet which ever and anon emitted nicotine incense that played about the sardonic features of the bold and adventurous wight who, accounted as per above description, might have been seen one bright morning in early autumn wending his solitary way along a beautiful road that led in the direction of—. But, to descend from Fenimore-Cooperisms, I may premise that having resolved upon a day's photography, I had selected the home district for my peregrinations, persuaded that a contemplation of nature as she might be seen out of the beaten track would prove mentally as interesting and photographically as satisfactory as if I had elected to subject her to the smallest stop of all my three eyes at the seaside, or up the river, or at any one other of the more or less distant places which are overrun by lovers of the picturesque, mainly, I suppose, because they are distant. So I had declared for the metropolitan county.

I have always held that Middlesex, like her eastern neighbour, is a badly maligned shire. In spite of bullet-headed jerry builders and soulless railway contractors, you may, within eight or ten miles of the Landseer lions, encounter Dame Nature under aspects as secluded, as emotional, as absorbing, as she is to be found in any other part of the kingdom. The opinion of Charles Dickens—himself an enthusiastic lover of outdoor beauty—upon the grandeur of the view from the Hampstead flagstaff, though often quoted is never gainsaid. This same staff is but three hundred yards or so beyond the limits of a two shilling cab fare, and Palmer's Green Station on the Great Northern Railway is barely six miles from King's Cross, and yet, when I had turned my back upon the unpretentious little edifice and swung round to the left, thus gaining the main Enfield road, I might, if I had not been perfectly well conscious of the contrary, have imagined myself ten times six miles away from "the madding crowd's ignoble strife," so thoroughly peaceful and rustic was the scene. Pondering thus, as the American novelist already named might have phrased it, I was reminded of a picture I had seen in *THE BRITISH JOURNAL OF PHOTOGRAPHY*, I think, some two or three years ago. It was a process reproduction from a negative by, if I recollect aright, Mr. Dunmore, and represented Ward's Farm, which abuts on Millfield-lane, Highgate—a spot beloved of Coleridge and many of his illustrious contemporaries. I can well imagine that a print from the negative would have been a charming picture; and yet Millfield-lane is actually inside the radius! Londoners are blind to the natural beauties within rifle shot of their front doors. "Absurd!" they say, "who ever heard of a photograph of Millfield-lane? You never see it in the shop windows; nobody buys it." True, with such a name nobody would. Mr. Dunmore made a mistake in nomenclature; he should have called his picture, "Ambleside," or "Rydal Mount," or "Llwmddfon, North Wales," and the result, if less satisfactory to him, would have vastly more impressed the common herd. But I digress.

Resisting at this early stage the temptation to uncup upon a pretty little thatched cottage, which is a familiar landmark at this part of the road, I sped on, and veering to the left at the first finger-post, quitted the charming highway for a lane hardly less sweet. Half a mile's plodding brings one to Winchmore Hill, which, though sadly marred by the bricks and-mortar Vandal, is still in parts amusingly primitive, and boasts its green, and duckpond, and Friends' Meeting House. There is a footpath through Winchmore Hill Wood, which is private property, and liberally planted with awful boards bearing divers legends in small type with the words "Notice" and "Law" of a higher fount. In this vicinity—for obvious reasons I suppress the exact spot—there is a cottage of which I was bent upon securing a negative. Tradition, in the guise of a lore-laden friend, had assured me that this same structure boasted an antiquity measured by centuries, and that in the gruesome days when Dissenters were subject to persecution at the hands of their dear brethren of the Establishment, recourse was had to the seclusion of this cottage for the holding of the forbidden services. If the tale is true, the selection did our Dissenting ancestors great credit, for in those times no better secret

meeting place could have been chosen—hidden away as it was and is from all the great highways in a small forest, intersected by only a footpath.

Arrived at the cottage, I unpacked and proceeded to take aim, when the door opened and the lady of the house appeared. Did she mind me taking her cottage? Oh, no, not at all! But, wondrous to relate, she did not evince the smallest anxiety to be in it. Something unusual, I mused, perhaps she's been in it many times already? I didn't inquire, for she had disappeared; probably, you will say, she was sighting you through the window—more likely she was peeling the potatoes. However, having repacked, I went on my way. The cottage is a one storey erection, with a tinge of the ecclesiastical in its architecture, and pretty to look upon, being almost hidden by ivy and creepers. For this latter reason, I suppose, the negative turned out disappointing—there being no sharp lines save in the diamond-paned windows and chimney-pot. It would have made a better water-colour sketch than a photograph.

Emerging from the wood I turned to the right, along a charming lane called after friend Reynard. A few yards brought me to a cattle pound. A stone's throw farther on, I came to another standstill, and exposed a plate upon a thoroughly pleasing bit, to wit, a row of ancient cottages standing well back from the road, supported on the right by a group of sombre trees and on the left by a Lilliputian alehouse. A butcher boy watched my operations with stolid interest. In order to get him out of the very mouth of my lens, I sweetly asked him if he would like to be in it. "No," quoth the blue-bloused one, "it 'ud cost too much." I vow that I bore no resemblance to the gentleman one occasionally hears of in the police-court, who charges you so much for taking a negative of your house, and unfortunately forgets to send you the prints. The knight of the marrow-bones and cleaver declining to be in it, I not unnaturally suggested he should be out of it, a piece of advice which he took in had part. However, it served my purpose, for he shuffled away from my camera before a specially selected glance of scorn with which I favoured him, and I made my exposure amid a running fire of uncomplimentary criticisms upon my person and paraphernalia.

Once upon a time I used to believe that the saddle of a bicycle afforded the finest vantage spot one could have wherefrom to appreciate and study scenery. As a photographer, I must qualify that belief now. The cyclist sees and admires only the outlines of a picturesque landscape—it is reserved to the pedestrian to pick out the details, the contrasts, the proportions, and all the varied "filling in" of the picture. If, upon this September morning I had been astride two or three wheels, instead of afoot, it is highly probable that I should have missed the sight of a serenely beautiful bit of still life. Across a low fence I looked upon a smooth expanse of comely park-land well studded with mighty oaks, watered by a miniature lake, and dotted with groups of young deer. Truly a perfect pastoral, and worthy of any of the great grass counties from Nottingham to Surrey. The south-west wind was at my back as I jogged past the park. Was it only fancy—that deep booming sound, or was it the real roar, mellowed down by distance, of Big Ben, seven miles away according to the flight of the crow, that soured up this leafy lane to remind me that the glories upon which I gazed were well within the beat of the Metropolitan police? Verily, I repeat, Middlesex is a maligned shire.

Quitting the precincts of the park, I made a slight detour Londonwards, and ambled through the old-world village of Southgate. There is much that is interesting about this still untouched pre-Victorian spot, untouched, that is, by the hand of the improvement commissioner or smug parochial innovator. Just where the road broadens into the green and is bounded by pretty, old-fashioned, red-roofed houses, a fleeting glimpse of English village life may still be had; stray geese and cattle dot the grass, itinerant hawkers *en route* for Hertfordshire cross the scene. The one or two tradesmen pursue their occupations in the lethargic and leisurely fashion peculiar to the provinces; there is an all-pervading drowsiness in the air; a couple of agricultural looking wayfarers are sitting outside the hostelry, pots in hand; whilst here comes an impossible spectacle in town—a walking funeral—and London is only at the bottom of that hill.

Turning my back upon dear Old Southgate I made for Colney Hatch *via* the lane of that name. The Dukes of Buckingham formerly had a house here, and Leigh Hunt used to live on the opposite side of the road. The autumn foliage was a mass of gorgeousness, and a noisy colony of rooks that inhabit a lofty clump of trees hard by were in fine vocal form. The Chapel Cricket Fields here have given many a famous wielder of the willow to the county—notably the Walkers, who practically claim the neighbourhood as their native heath; and the Hearnese to Kent. Half-way down the lane a fine view is obtained, Barnetwards, across a truly typical valley. At the foot of the hill is a mild imitation of a waterfall, whilst in spring the cuckoo haunts the spot—as well he may, for the Walker demesne on the other side of the fence might make a Job envious.

At New Southgate one almost feels as if he had suddenly stepped from the country into town at a stride. I hurried past the asylum with all haste, and after a parting glimpse of the Alexandra Palace was not sorry to turn into Friern Barnet-lane and leave civilisation behind me once more. And here I may remark upon the high favour which this division of the county seems to enjoy amongst some of the great trade houses. At Old Southgate I saw a name not altogether to be disassociated from a western square; at the very entrance gates of New Southgate, looking across a few meadows, I descried on the top of a little hill a pile of buildings obviously dedicated to the worship of the art, and somewhat sug-

gestive of Regent-street and Cheapside. Again, happening to glance towards my left, my eye fell upon the words "Trade Printer," over a doorway; whilst, later in the day, in the town of horse fairs, I happened across the works of another firm whose name recalls Baker-street, together with many other evidences of the fact that the "northern heights" are a desirable location for photographic printing, as well as manufacturing purposes.

Friern Barnet-lane is a delicious survival, recalling in many respects some of those delightful nooks on the Middlesex side of Burnham Beeches. There is a little church here upon which I exposed a plate. Not having a guidebook handy, and being unlearned in architectural styles, I am unable to say to what order the church belongs, but should call it early nineteenth century. The church is surrounded by a belt of trees and a well-kept churchyard. The immortal Stoke Pogean elegy immediately occurred to me, as also the unpleasant piece of prose that the south-wester had not belied its auguries, and that it was raining heavily. It is astonishing how many good negatives are secured under adverse circumstances. I'm sure I have run across "some of the finest in the world," which have been taken "in pouring rain, sir." I confess to entertaining a certain amount of doubt on the point as to how far rain would interfere with a quickly exposed plate, but of its utter powerlessness to interfere with one lengthily exposed I obtained excellent evidence on this occasion, for I gave the church ten seconds with the smallest stop, and secured a perfectly clear, sharp, and brilliant negative, more suggestive of sunshine than showers. After this I resumed my journey, crossed the great North road at Whetstone, turned down a narrow lane, and after a mile or so of uphill and collar work, found myself in the village of Totteridge, which is as rural as Southgate, only more so. It being past midday, and my kit beginning to assert its weight, the "detachment" halted and billeted itself for a couple of hours at—not to put too fine a point upon it—one of those places of public entertainment which Mr. Hardcastle's guests in *She Stoops to Conquer* imagined that worthy old gentleman's house to be.

Totteridge Church has a square wooden tower—rather a curiosity for the district, I should say—and as it is a quaint little edifice, prettily situated and embosomed in a well wooded spot, I uncapped upon it, and after development had no reason to be ashamed of the negative. The next stage of this adventurous tour was Barnet. The fair was on at the time, but things were rather depressed, not to say moist, except in the horse field. Politely but firmly refusing to take any of the awing and shooting gallery ayrens, either for better or worse or photographically, I penetrated the howling mob, emerged safely, and strode up the hill to the town. Barnet is—but no, perish the idea! this is not a guidebook. I halted at Hadley Corner, and exposed a plate upon a doubtless very interesting subject, only I didn't exactly know what it was, and there was no one handy to tell me. Here it is: In the background are houses and a turnpike gate; foliage and fences right and left; in the middle of the picture the stump of a tree guarded from injury by iron railings. I had an idea that this was more or less associated with the king-maker, and the obelisk that marks the spot where the great baron fell; but it was only an idea, for nobody seemed to know, and as I have before remarked (or meant to remark) these notes are not based upon guidebook gleanings.

Hadley Woods were but the toss of a pebble away. I spent a delightful two hours in the shadow of their silent glades, and as I had only one plate left much cogitation was necessary before I could prevail upon myself to expose it. When I did at length uncup, it was upon what I conceived to be an idyllic stretch of woodland. Doubtless I was right; it was a delightful picture—if I had secured it. Unfortunately, I subsequently discovered that I had vastly under exposed the plate, and then I remembered it was late in the afternoon when I had taken the cap off, that the sun was low in the heavens, that it had been raining, and that a mist was rising—and, in short, that I had fallen into the old, old error of misjudging and ignoring conditions. Six miles of diversified, sometimes wild, always beautiful, country, brought me to Palmer's Green Station again, just as the stars were glimmering through the sky; tired, of course—as who would not have been?—but delighted with my miniature outing; more than ever in love with the sylvan sweetness and rural repose that still remains in Middlesex, and so full of admiration for the never palling beauties of nature—her perennial charms and undying glories—as to be seriously inclined to drop into poetry in the manner of Silas Wegg—or Mr. Cobb.

MARSTON MOORE.

PHOTOGRAPHERS' APPRENTICES IN SWITZERLAND.

At a recent General Meeting of the Photographic Society of Switzerland, held at Olten, the President delivered the following address:—

"At the first meeting of our Society, held on August 1, 1886, you invited the managers to consider the question of apprenticeship, and to report thereon to the General Assembly in the spring of 1887. The managers have acted upon this invitation, and each of them has collected information as to the conditions of apprenticeship in various establishments. At the meeting of the managers of February 28, 1887, at which M. Pricam and M. Gysi unfortunately had not the power to take part because of ill-health, the information gathered was compared, and it was ascertained that the conditions could not be worse in any profession. In the matter of the duration of the apprenticeships the times fixed are completely arbitrary, so it is evident that good establishments often cannot take on as assist-

ants young men who after their apprenticeship present themselves as accomplished photographers, or at all events they cannot pay them the salary which they ask. We know of one case in which a photographer was created in the short space of two months in consequence of paying a thousand francs as the premium for apprenticeship, and in other cases the time has not been longer than one year or a year and a half; apprenticeships of more than two years' duration are very rare. If we think of the experience necessary to learn the three branches of photography—camera work, printing, and retouching, with all the operations in the dark room—before an apprentice can become accomplished in these different branches, it will readily be seen that the periods mentioned are too short to turn out good photographic workmen. We do not know why photographers should not occupy as much time in learning their business as persons who enter all the other professions. According to statistics collected by the Industrial Society of Switzerland in the year 1886, printers, lithographers, mechanics, goldsmiths, and *bijoutiers*, usually pass through an apprenticeship of three and a half or four years.

"There is another important point to which we wish to draw the attention of our members. In fixing so arbitrarily, as at present, the duration of photographic apprenticeship we are discrediting our own profession, we are degrading it in the eyes of the public, and placing it upon the lowest level.

"The managers have, therefore, to suggest regulations for apprenticeship similar to those which exist already or are on the way to be introduced into other professions, and they think that the adoption of the regulations will be a means of putting an end to the present system, and to raise the level of photographic apprenticeships. The project has been discussed by the managers, and in submitting it to you as the principal subject to be considered at our meeting to-day, we have the honour to recommend you to give it your sanction.

"RULES OF APPRENTICESHIP FOR THE MEMBERS OF THE SWISS SOCIETY OF PHOTOGRAPHERS.

"1. The young man who wishes to be apprenticed shall produce certificates that he has studied at a secondary school, or equivalent place of instruction, or at all events that he has been eight years at school.

"2. As a general rule, no young man shall be accepted as apprentice if he be under fifteen years of age. Exceptions, however, may be made in favour of young men specially gifted, who may then be taken on one year earlier.

"3. Each apprentice must have four weeks' preliminary trial to see whether he is suited for the profession, and whether the profession is suited for him. During this time he may be rejected or may himself renounce the apprenticeship, and in these cases no indemnity can be claimed on either side.

"4. If at the expiration of the time of trial the two parties are satisfied, they shall make a contract of apprenticeship.

"5. The apprenticeship shall not be for less than three years.

"6. The master must initiate his apprentice into all the work carried on in his establishment, and teach him everything fairly, and see that the apprentice changes his branch of work at times appropriate to the circumstances.

"7. The master must also arrange matters that the apprentice can instruct himself out of working hours, above all in matters of chemistry, physics, drawing, and eventually in that of modelling, at least so far as local circumstances permit.

"8. The master must take care of the health of his apprentice, and not injure his bodily development by working him beyond his strength.

"9. At the end of his apprenticeship the apprentice shall submit to a practical examination by a member of the Society appointed for the purpose. Before being examined he must present a certificate that the time of his apprenticeship has expired.

"10. If the result of the examination is satisfactory, the apprentice shall receive a certificate of efficiency; if unsatisfactory, it shall be refused. (The Society will establish special rules in relation to this examination.)

"11. Members of the Society are forbidden to have more than two apprentices at the same time.

"All the members of the Swiss Society of Photographers shall pledge themselves to observe and apply these rules, after they have been passed by the Society.

"They shall pledge themselves also not to take on any workman who is not in possession of a certificate of efficiency, at least if he cannot justify himself by the fact of having served his apprenticeship before these rules came into force.

"Finally, the members shall engage not to receive any apprentice who shall have been employed by another photographer and left him reprehensibly without serious reason, before the conclusion of his apprenticeship.

"Deliberated and unanimously adopted by the Society, at its second General Assembly, at Olten, April 25, 1887."

SILVER SUBOXIDE.

In the number of the *Berichte* recently issued (May 23) is a communication from Dr. Otto von der Pforden, in which he considers "that he has proved with certainty the existence of compounds of suboxide of

silver." Having confessed that Wöhler's original method with citric acid is out of the question, he gives two methods of preparation which are in some respects new.

In one of these he adds sodium hydrate solution to neutral tartrate of soda containing some nitrate of silver and obtains a black powder, "which is at all events the suboxide of silver in combination with an organic acid, probably tartaric," and at the same time there is "probably formed a mixture of organic acids." The powder cannot be filtered; it is decomposed by almost every reagent, and it is purified (*sic*) by washing it by decantation with a solution of sodium sulphate! This tartrate, by the action of caustic alkalis, yields the suboxide which is stable in presence of caustic potash, but, singularly enough, is decomposed by pure water.

Notwithstanding the extreme difficulty, indeed the impossibility, of washing such oxides free from alkalis by decantation, and the importance that in this case every trace of organic matter should be removed, no mention is made of any special precautions in this direction.

In spite of the high degree of probability that metallic silver is contained in the product, and that oxygen is mechanically retained, no criterion (beyond assertion) is given of the homogeneous character of the suboxide.

The interest of the paper centres on an accurate analysis, which to be satisfactory must—for manifest reasons—be made on tolerably large quantities of substance; and yet no details whatever are given of such an analysis, except that a certain volume of a very dilute solution of permanganate of potash was used for the titration. And even if these matters were quite satisfactory the problem is a much more complicated one, for we have in the case in question one or all of the following substances:—

- (1) Extremely finely-divided silver;
- (2) Oxide of silver;
- (3) Suboxide of silver.

Each of these retains oxygen, moisture, and alkalis with very great tenacity, and of the behaviour of such physical associations with reagents very little is known. Unless, indeed, it is possible to prepare, as Wöhler attempted to do, a pure salt of the suboxide, of definite composition, the problem is almost incapable of a satisfactory solution. Of course the communication is only given as a preliminary one, but the composition of the suboxide (and any remarks in this note apply equally to the sub-sulphide) is definitely stated, no lack of details of minor importance are given, and the behaviour with various reagents.

My object is not to criticise the paper, which is indeed more open to criticism in parts not touched upon, but only to point out that the conclusions drawn are not warranted by the evidence.

G. H. BAILEY, D.Sc., Ph.D., *The Owens College*.

RECENT PATENTS.

APPLICATIONS FOR PATENTS.

No. 9068.—"Improvements relating to Magic Lanterns." G. CARETTE.—*Dated June 25, 1887.*

No. 9096.—"Improvements in Shutters of Lenses for Taking Instantaneous Photographs." C. KNIGHT.—*Dated June 27, 1887.*

PATENTS COMPLETED.

IMPROVEMENTS IN OR CONNECTED WITH PHOTOGRAPHIC CAMERAS.

No. 9645. THOMAS SAMUELS, Monken Hadley, Middlesex.—*July 26, 1886.*
My invention relates first to improvements in apparatus (such as that for which former Letters Patent were granted to me, dated February 15, 1883, No. 843) for holding a stock of dry plates or films, and exposing them in succession in the photographic camera. This apparatus consists of two boxes or compartments juxtaposed and communicating, and provided with a dark shutter acting also as a means of propelling the plates or films in succession from one box to the other.

My present improvements have for their object, first, to provide a means (in addition to, or in lieu of, that described in the specification of my former Letters Patent) whereby the canting of the sheathed plates or films in the receiving box or compartment may be effected. For this purpose I provide, on the baseboard opposite the receiving box or compartment, a means of forcing backwards or canting the plates or films to make room for the incoming plate or film. Such means may consist of springs, or of lever arms on a rock shaft, or of a combination of the two, the same being so situated as to act on the sheath or holder, and not upon the plate or film, for the purpose of canting it, and so as not to obstruct the passage from one box or compartment to the other.

My improvements have, secondly, for their object, to adapt the apparatus to be applied to cameras to which the apparatus described in my aforesaid specification could not be conveniently adapted; also to avoid any projection of the dark shutter beyond the end of the apparatus when drawn back for exposure of a plate, and to avoid the necessity for providing against the leakage of light into the apparatus on drawing out the said shutter; also to enable the capacity of that form of the apparatus which consists of a single box divided into two compartments to be doubled without increasing its dimensions, whereby it is adapted for tourist as well as for studio use.

The improvements consist in placing the exposing aperture opposite the receiving compartment, so that the plates or films will be brought by the shutter to the exposing position instead of being moved thereby out of exposing position, as in the former case. To enable this to be done, and to

make the shutter wholly contained within the apparatus, I use a shutter of thin sheet metal, which is actuated by a sliding rod connected to its front or outer face at a point near its leading edge, the rod passing through the exposing aperture, and through a suitable guide outside or along the front face of the apparatus without projecting beyond the end thereof.

The propelling part of this shutter is situated at the rear edge of its inner face, the sheathed plate or film resting, whilst being propelled, against the shutter, and being left by it opposite the exposing aperture on the withdrawal of the shutter, spring detents being provided, if necessary, to prevent the plate being carried back with the shutter. To permit this shutter to work easily, springs are provided, against which the plates, pushed forwards towards the shutter, rest, so as to relieve the shutter of part of the pressure during its motion. On the shutter reaching the end of its motion, these springs are pushed aside, and the front plate allowed to come forward into position against the shutter to be propelled thereby. The old form of shutter may, however, be adopted, with the addition of the sheet metal portion herein described.

The canting of the plates in the receiving compartment, in order to allow another plate to come in front of them, is effected either by the levers and rock shaft above referred to, operated by hand, or by similar levers actuated automatically by the shutter itself, the actuating parts of the shutter and the levers being so formed and arranged as to be inoperative during the motion of the shutter in one direction.

In order to enable both compartments to be filled with plates or films, and so double the capacity of the apparatus, I provide a second passage between the compartments at the back, and also a means of propelling the plates from one compartment to the other in the opposite direction to that in which they are moved at the front, so that the plates will be caused to perform a complete cycle of motion.

Such means may consist of a sliding catch actuated from the outside of the back cover of the apparatus, and engaging at the inside with the sheath of the rearmost plate or film for the purpose of moving it from one compartment to the rear of the plates in the other compartment. This sliding catch may be worked alternately with the shutter, or it may be connected therewith, so that the two will work together. The combined working may be effected either directly by hand or through a mechanical movement, such as a transverse shaft gearing at front and back by rack, slotted cams, levers, or other motion with the two parts to be operated.

The springs by which the plates are pressed forwards in both compartments are necessarily modified to adapt them to the altered circumstances, and they are so placed, and act on the plates in such manner, as to produce the least pressure against the sliding shutter compatible with holding the plates in their proper position.

My invention has, thirdly, for its object to dispense with the division of the apparatus into two compartments, the whole of the plates being placed in a trough-like compartment in front of one another and transferred successively from one end of the series to the other as they are exposed. This is effected by the use, in combination with a shutter constructed and operated as above described, of a flexible bag-like chamber enclosing the top of the trough-like compartment above referred to, through which flexible chamber the plates are transferred from one end of the series to the other.

The invention has further for its object to dispense with the usual rack and pinion or screw motion used for focussing, and consists in a lever adapted to engage with the focussing slide (which carries the movable part of the camera) at different points thereof, the angular motion of said lever producing a rectilinear motion of the slide, the lever working on a movable centre, or other means being provided of allowing for the difference between the two motions.

The claims are as follows:—1. The employment in a photographic changing back of the kind described in the specification of my former patent or of the kind herein described, of a rock shaft and levers (either with or without springs) arranged and operated as described, for the purpose of canting the plates, as specified. 2. The employment in a photographic changing back of the kind described in my former patent of springs applied as described for the purpose of canting the plates automatically, as described. 3. The employment in a photographic changing back of the kind herein described of levers actuated by projections on the shutter, and applied so as to act on and cant the plates, the action of the levers being dependent on the motion of the shutter, as specified. 4. In a photographic changing back, consisting of two juxtaposed compartments as herein described, a shutter working wholly within the apparatus, and actuated by a handle or bar connected to the front of the shutter, and passing through the exposure aperture, and sliding along the front of the changing back, substantially as specified. 5. A sliding shutter for a photographic changing back of the kind described, working wholly within the two compartments of the back, and consisting of a thin metal plate provided with a projection on the rear face in such position as to carry the sheathed plate or film from one compartment to the other, whilst the same is resting against the shutter in the manner described. 6. In a photographic changing back of the kind described, the combination with a shutter provided with a projection on its rear face for propelling the sheathed plate or film whilst the same is resting against the shutter, as described; of springs acting in conjunction with the said projection for preventing the next succeeding plate or film advancing until the shutter has been moved back into position to receive it, the springs being moved back out of the way by the shutter, substantially as described. 7. In a photographic changing back of the kind described, the combination with a shutter, acting also as a carrier, for propelling the sheathed plate or film whilst the same is resting against it, as described; of spring detents, applied as shown and described, to prevent the shutter, on its withdrawal, drawing back with it the plate or film which it has just propelled. 8. A photographic changing back constructed and operating as herein specified, and comprising a box divided into two compartments communicating at back and front as described, and both filled with sheathed plates or films, a shutter acting also as a carrier for propelling the sheathed plates or films successively from the front of the one compartment to the front of the other as described; plate-canting levers arranged and operating as described; a drag hook or catch carried by a slide working in the back cover as described, for moving the rearmost plate or film from the one compartment to the other in the opposite

direction to that in which the foremost one is moved by the shutter, and springs attached to the back cover, and pressing the plates or films forwards in both compartments, all combined for operation substantially as shown in the drawings. 9. The combination with a changing back, consisting of a box divided into two juxtaposed compartments communicating at front and back, as described; of a drag hook or catch projecting into the one compartment, and attached to a sliding bar fitted to work in a groove in the interior of the part of the back cover opposite the one compartment, and in the exterior of the part opposite to the other compartment, so that the catch and the means of operating it are not opposite the same compartment, and there is no slot directly through the cover, as described. 10. A photographic changing back, consisting in the combination with a trough-like compartment containing a series of plates placed in front of one another of a flexible or bag-like chamber communicating with the said compartment, and of a means of lifting the foremost plate partly or wholly out of the compartment into the bag, so as to enable it to be seized from outside the bag and transferred from the one end of the series in the compartment to the other, as described, whether such means be a shutter acting also as a lifter, as described, or a simple lifter only, substantially as specified. 11. The improved motion for operating the focussing slide, consisting of a lever pivoted to the baseboard and engaging with the said slide as described or *vice versa*, the varying angle of the lever relatively to the slide being allowed for in one of the ways specified.

IMPROVED ARRANGEMENTS FOR COATING GLASS OR OTHER SURFACES USED AS A SUPPORT FOR PHOTOGRAPHIC EMULSIONS.

No. 9886. JAMES WILLIAM THOMAS CADETT, 84, Grove-lane, Camberwell, London.—July 31, 1886.

My invention is intended for coating glass or other surfaces, used as a support for photographic emulsions, with such photographic emulsions, where such coating is done on travelling or moving surfaces in one direction. My invention is particularly applicable to the tables or setting surfaces now in use where a cord or cords, or chain or chains, or band or bands, or other moving surfaces or arrangements, carry the glass or other surfaces to be coated in one direction while being coated.

My invention has for its principal objects: Firstly, the even spreading of the photographic emulsions on the surfaces to be coated, after the photographic emulsion is laid down, not necessarily evenly to begin with, on the surfaces to be coated; and, secondly, means for ensuring a proper and unfailing delivery of photographic emulsions to the surfaces to be coated.

In combination with the above-mentioned tables or carrying arrangements for the surfaces to be coated, I use a rod or rods, or surface or surfaces, or tube or tubes, arranged so as to rest across the surfaces to be coated without touching such surfaces to be coated, excepting at such points or places as may be necessary to support such rod or rods, or surface or surfaces, or tube or tubes.

The rod or rods, or surface or surfaces, or tube or tubes, is or are arranged at such a suitable distance from the surfaces to be coated, that when photographic emulsions are put on the surfaces to be coated, and are carried by the above-mentioned tables or carrying arrangements under the rod or rods, or surface or surfaces, or tube or tubes, the photographic emulsion is spread by capillary attraction across the surfaces to be coated, and thus a practically even film obtained.

For putting down a suitable and proper amount of photographic emulsion on the surfaces to be coated I prefer to use an open chamber with a series of plugs or valves, such plugs or valves when in use being kept in action by suitable power so as to intermittently and continually open and close, and thus lay down a suitable quantity of photographic emulsion, such above-mentioned chamber with plugs or valves being filled to a suitable extent with photographic emulsion, and such chamber being placed in suitable position over the surfaces to be coated. Arrangements can be made to keep such chamber warm by fire, hot water, or hot air or gases, and the above-mentioned rod or rods, or surface or surfaces, or tube or tubes can also be kept warm by hot water, or hot air, or gases passing preferably through it or them.

The claims are:—1. The use of a rod or rods, surface or surfaces, or tube or tubes, substantially as described, arranged so as to rest across the surfaces to be coated as described, in conjunction with arrangements for moving or carrying the surfaces to be coated. 2. The use of plugs or valves for intermittently opening and closing, substantially as described. 3. The use of the said rod or rods, surface or surfaces, or tube or tubes, as mentioned in claim 1, in conjunction with the plugs or valves for intermittently opening and closing, substantially as described.

IMPROVED PHOTOGRAPHIC CAMERA.

No. 4718. CHARLES CUSWORTH, 16, Ellington-street, Islington.—March 30, 1887.

The objects of my invention are:—

- 1st. To facilitate the erection and closing down of that part of a photographic camera known as the Front.
- 2nd. To expedite focussing.
- 3rd. To enable the front to be fixed at any angle to the baseboard; and
- 4th. To facilitate the fixing of the rising front at any required distance from the focussing screen.

I carry out the first of the said objects by attaching the bellows of the camera to the front, and allowing the front to slide up and down a slotted frame provided for its support.

The second of my objects is carried out by attaching the front to its supporting frame, which in its turn is attached to sliding pieces, and allowing the supporting frame to slide backwards and forwards in a carrying frame, which has a rack and pinion movement attached to its underside, thus giving, by means of the rack and pinion action, a to-and-fro movement to the front.

The third object is of a twofold nature, and is carried out by (a), centering the supporting frame into the sliding pieces, thus allowing the supporting frame to rotate; (b), attaching to the sliding pieces, and at a distance from the centre, a slotted strip by means of a pin; the said slotted strip extending up-

wards past the side of the supporting frame. A milled headed screw is attached to the side of the supporting frame and slides in the slotted strip. By means of this milled headed screw and slotted strip the front may be held firmly in any desired position.

The fourth of my objects is carried out by attaching to the side of the sliding piece a block on the underside of which is an inclined plane. The fulcrum of a lever is also attached to the side of the sliding piece, and on the side of this lever is another inclined plane.

IMPROVEMENTS IN PHOTOGRAPHIC CAMERAS.

No. 6076. WALTER CLARK, New York, United States.—April 26, 1887.

THE object of my invention is to improve and render more certain the action of the devices which produce the instantaneous effect in photographic cameras, and also to improve the devices for focussing.

My invention consists of a camera box, preferably of the kind having the lens and its tubes within the box, provided with a hinged lid, which, when lifted, carries with it a ground-glass focussing plate which is maintained in a horizontal position by a certain arrangement of links, and is always at the same distance from the mirror upon which the incident rays are received that the said mirror is from the surface of the sensitive plate. The ground-glass plate is also provided with a hood so arranged as to fold within the box when the lid is lowered.

My invention further consists in placing within the camera box, a drum revolving upon a vertical axis under the action of an adjustable coiled spring, controlled by a friction wheel, open for a portion of its cylindrical surface, and provided in the closed portion with a window for the admission of the light rays when the window passes the aperture of the lens.

My invention further consists of certain details of construction of the various parts to render their action more certain and efficient, and to ensure the entire exclusion of light from the dark chamber. These minor features will be more fully hereinafter set forth.

[The remainder of the specification could not be understood without reproducing the engravings.]

The claims are:—1. A photographic camera provided with an inner lid, to which is pivoted a revolving drum containing the focussing mirror; said inner lid being retained in place by a projection on the plate holder, substantially as described and for the purposes specified. 2. A photographic camera provided with a revolving drum mounted on a vertical axis and placed immediately behind the lens; said drum carrying the focussing mirror and provided with a window to admit the passage of light at the proper time through the lens to the sensitive plate, as herein described and shown. 3. In a photographic camera the hinged lid and ground-glass plate pivoted thereto and raised and supported by links; the parts being so arranged and adjusted that when raised the plate is always the same distance from the focussing mirror, as herein described and shown.

AN IMPROVED APPLIANCE FOR USE IN TREATING AND WASHING PHOTOGRAPHIC PRINTS AND PLATES.

No. 6353. The Hon. WILLIAM GIMSTON, Gorbamby, St. Albans, Herts.—April 30, 1887.

My invention has for its object to provide a simple appliance, by which the treating and washing of photographic prints and plates may be effected very efficiently and rapidly.

According to my invention, I provide a tray or receptacle, of any suitable shape, but made of perforated or reticulated material, such, for example, as perforated sheets of galvanized iron, or woven wirework, or papier maché, or earthenware with a number of perforations therethrough.

Into this receptacle the prints or plates to be treated or washed are placed, and in such treatment or washing the water or liquid is caused to pass through amongst the prints and out from the receptacle; for example, the receptacle may be placed in any common bath, and be withdrawn at intervals, so as to cause the water or liquid to run out from the receptacle, and carry with it the matter which has been removed from the prints or plates, or by which the prints or plates have been treated, or the receptacle may, for washing purposes, be placed in a stream of water. My invention is especially adapted for large photographic prints on paper, as the receptacle can be taken with the prints in it from bath to bath from beginning to end without handling, thus obviating the chance of tearing the paper.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—For and in treating or washing photographic prints and plates, a perforated or reticulated receptacle, through which water or liquids can be caused to pass without the necessity for handling the prints or plates, substantially as hereinbefore described.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

LAST Tuesday night, at a meeting of the above Society, held at 5A, Pall Mall East, London, Mr. William England, Vice-President, occupied the chair.

The CHAIRMAN introduced to the meeting Mr. Winslow Upton, Professor of Astronomy, Brown University, Providence, U.S.A.

Mr. G. L. ADDENBROOKE exhibited a camera stand made by Messrs. Sands & Hunter, which he said was the best he had ever seen; he then explained its principles of construction. He also exhibited a tourist's camera by the same makers, likewise a bamboo stand devised by himself.

Mr. SCAMELL asked if he knew the time required to unpack the stand and get it into use.

Mr. ADDENBROOKE replied that he did not.

Dr. JOHNSON exhibited a twill bag lined with indiarubber, to keep dust, damp, and light from slides. He had been trying in Holland a dark slide devised by Mr. Brown, of Clerkenwell, and had found it to be without fault, and that he could change the plates more rapidly than with an ordinary slide; it had also improvements in its springs, bringing the plates to absolutely perfect register.

Mr. W. F. DONKIN exhibited the camera with which of late years he had taken his Alpine views. In taking panoramic views, a class of pictures for which he cared little, he saw no use in a plumb line under the optical centre of the lens unless for objects abnormally close to the camera; with ordinary landscapes one view might be taken a few yards from its neighbour; he had done it often. The apparatus should always be carried knapsack fashion on the back, weight then being much less felt, but straps across the breast should be avoided; the straps over the shoulders should be broad. It was quicker to have a case for the stand, because then the legs could be pushed in anyhow, and there were no straps to buckle. His whole arrangement, with an Eastman's slide and the legs included, weighed fifteen pounds, for $7\frac{1}{2} \times 5$ negatives. A level was very necessary in mountainous countries, especially when setting up the camera on uneven ground, where the eye is often grievously deceived; his level consisted of a plumb line in shape of a piece of wire three or four inches long suspended alongside part of the woodwork of the camera. He thought Dr. Johnson's indiarubber cases to be good. Abney's plan of painting interior edges of the slide with glycerine to keep out dust was excellent.

Mr. T. SEBASTIAN DAVIS demonstrated his method of wrapping an indiarubber cloth round each of his camera slides, and so using it as to, all through the exposures and operations, keeping it from the direct light from the sky.

The CHAIRMAN kept each of his slides in a cardboard case.

Mr. W. E. DEBENHAM asked whether Mr. Donkin's plumb wire did not swing in the wind.

Mr. DONKIN replied that it did so sometimes, but the wind was then easily kept off sufficiently by the hand.

Mr. T. BOLAS put a question in reply to which all but one speaker said that circular spirit levels were very liable to get out of order quickly when in daily use.

Mr. DAVIS exhibited his camera made of blackened deal, which was also its own packing case. It was, he said, simple and efficient, and necessarily perfectly rigid.

The Chairman exhibited his travelling tent, in which he could develop 12x10 negatives, and which weighed five pounds.

Mr. SAMUELS said that a tent was handy to use as a packing covering for apparatus.

Mr. FOX SHEW exhibited some of the Balagny films, which, he said, had been popular now for two years in Paris, but did not seem to be much known in this country. They exhibited no structure at all, did not expand or curl up in the developing solutions, required no greasy or other after-treatment, and were treated just like glass plates, except that they must be alumed after developing, and must be quickly dried by means of methylated spirit with a little glycerine added.

Mr. E. COCKING announced that the meeting to consider the proposed new rules of the Society would be held on the third Tuesday in July.

The proceedings then closed.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At a meeting of the above Association, held at the Masons Hall Tavern, City, London, on Thursday, June 23, Mr. W. E. Debenham presided.

Mr. J. TRAILL TAYLOR said that he had received from Mr. Mayall his long-promised photograph in natural colours; he would exhibit it and let it speak for itself.

Mr. Taylor's likeness was then handed round, and it evoked some expressions not complimentary to the artist or the process.

The CHAIRMAN thought that something should be done by the photographic societies to make a stand against pretensions to take photographs in natural colours, because photographers as a body suffered by such public pretensions.

Mr. J. J. BRIGINSHAW said that the ignorance of daily newspapers about scientific subjects had much influence over the public in the matter.

Mr. TAYLOR had been looking at the Jubilee illuminations, and thought that lantern slides might be made to represent them by printing a dark positive on glass and afterwards pricking holes in the film where the lamps were, to represent the lights.

Mr. Atkinson exhibited a group of some members of the amalgamated photographic organizations, taken on the occasion of their visit to Watford on Jubilee Day. The meeting then broke up.

CAMERA CLUB.

On Thursday, June 23, a varied exhibition of lantern slides was given. Several visitors very kindly accepted invitations to favour members with a view of their work, amongst these being Messrs. J. B. B. Wellington, B. J. Wilkinson, W. England, and Major Nott.

The members exhibiting were Messrs. Gale, C. B. Wright, Brownrigg, Lyonel Clark, Ferrero, Dresser, Howlett, and Davison.

Two series were shown by Mr. Wright, one including some very fine views in Norway, and the other representing work in North Devon.

Mr. Gale and Mr. Wellington both exhibited some very fine slides, chiefly landscape and country scenes with figures.

Mr. Wilkinson sent by request half a dozen slides which were bracketed with a similar number by Mr. Burton Barber to receive the highest award at the last annual competition of the Amateur Photographie Field Club.

Mr. W. England exhibited slides from negatives taken in Shew's fixed focus detective camera. The transparencies were full of detail and marvellously sharp throughout.

Slides made from some of Major Nott's fine negatives of animals taken in the Zoological Gardens were shown, as also some similar work by Mr. Dresser.

During the evening some very handsomely got-up lenses called "Star" lenses, just introduced here under the agency of Messrs. Hinton & Co., were handed round and critically examined. Attention was also drawn to photographs of the Jubilee procession, taken by Messrs. D. P. Rodgers and Lionel Clark.

Club excursions for members and friends have been arranged for Saturday, July 9, to Eynsford and Lullington; Wednesday, July 13, to Rochester; and Saturday, July 23, to Pangbourne for Streatley and Goring.

NORTH SURREY PHOTOGRAPHIC SOCIETY.

The usual fortnightly meeting of this Society was held at the Greyhound Hotel, Dulwich, on Wednesday evening, June 22,—Mr. Eskell in the chair.

Mr. James was elected a member.

According to arrangement, members brought with them their complete outfits for work in the field.

The more important features of the different kits were explained, which led to an interesting discussion.

The next meeting will be held on July 6.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

At the meeting held at Myddelton Hall, Islington, N., on Friday, June 17, Mr. J. Traill Taylor, President, in the chair, Messrs. G. McCourt and F. T. Parsons were elected members of the Society.

Mr. A. PRINGLE gave an account of the preparations that the Local Committee in Glasgow of the Photographic Convention of the United Kingdom had made for the reception and entertainment of the members attending the meeting in July.

Mr. E. DUNMORE then delivered a lecture on *Photography Past and Present* [see page 390].

Mr. A. PRINGLE said that Mr. Dunmore had referred to a class of photographers who cared little for the artistic qualities of the pictures they produced so long as they were technically good as photographs. There was, however, a class among amateurs who studied the artistic side and neglected the technical, and seemed to think if the composition of a picture was good that the quality of the negative was of little importance. He agreed with Mr. Dunmore on the importance of art in connection with their work, but at the same time thought too much stress could not be laid on the importance of thoroughly mastering the difficulties of development. No picture was ever the worse for the negative being technically perfect, and he thought that it should be the aim of every photographer to produce work perfect technically as well as artistically. He had recently been devoting much time to photo-micrography, in which work the technical branches of photography were all important.

Mr. J. NESBIT thoroughly appreciated the remarks Mr. Dunmore had made with reference to the difficulties that photographers had had to contend against in the wet process days. He commenced photography in 1853, and had not only practised the wet process but several of the dry processes. He did not feel so satisfied with the work he had recently produced as with that of times gone by, as he felt that he had not kept pace with the opportunities now afforded for attaining perfection.

Mr. A. MACKIE said that, while he quite agreed with Mr. Dunmore on the importance of the art side of photography, he also agreed with Mr. Pringle's views as to the importance of a thorough grasp of the technique. He thought that amateurs often failed, especially in their attempts at portraiture, from their inability to keep their minds free from matters appertaining to the dark room at times when the whole attention should be given to the subject of the picture and its lighting and composition. Amateurs, too, were too often slaves to some particular form of developer, and made their exposures to suit that developer. This he thought a wrong method of proceeding, as there was no developer that would equally suit every plate or every subject. The developer should be modified according to circumstances. He could not impress too strongly the importance of remembering that the lens only produced the picture as it appeared, and that therefore, until the plate was exposed, the undivided attention should be given to matters pertaining to the picture as a picture, leaving development for after consideration.

Mr. E. CLIFTON thought that we were too fond of trimming our prints to regulation shapes and sizes without reference to their suitability to the subject. Frequently a charming picture might be produced by taking a small portion from a plate which was unsatisfactory as a whole.

Mr. J. JACKSON spoke of his experiences with wet plates and also with dry plates made by himself by the earlier bath methods, using tea, coffee, beer, &c., as preservatives. He fully appreciated all that Mr. Dunmore had said as to the difficulties and inconveniences of wet plates.

Mr. W. F. COX said that the technical part of photography could be mastered by a little serious study. He thought that the art difficulty could only be met by a course of study in an art school.

Mr. PURTON said that, in the Colonies, the silver bath was still used in many studios for portraiture, and in all for copying. Very excellent dry plates were now being made in Australia, but they seemed especially suitable for portraits and did not give the vigorous image wanted for landscapes. He considered that the Colonists held their own in portraiture but not in landscape work, but this was probably because the scenery was comparatively uninteresting.

Mr. HEALEY said he was probably the oldest photographer present. He commenced in 1847, and had first worked Daguerreotypes. He had also used the wet process, and had taken instantaneous portraits by it. Hill Norris's were the first dry plates he used, but later on he had made collodion emulsion.

For some years he ceased to practise photography, but the conveniences of gelatine had induced him to take up again his old hobby.

Mr. J. OAKLEY spoke of the improvement in the picture to be obtained in some cases by taking a low point of view. He thought that many amateurs failed to do their best by attempting too many plates. He thought they should do less work, but it should be more carefully considered.

The proceedings terminated with a vote of thanks to Mr. Dunmore.

Next meeting, on Tuesday, July 5, a technical meeting.

DERBY PHOTOGRAPHIC SOCIETY.

The members of this Society held an excursion to Cromford and Matlock on Saturday afternoon last, when some excellent negatives were obtained, the weather being favourable and the attendance a good one.

The excursion next Saturday will be to Miller's Dale for Cressbrook Dale.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

The monthly meeting of the above Society was held in the Technical Schools, Bridge-street, on the 23rd instant,—Mr. W. J. Harrison, F.G.S., in the chair. There was a good attendance.

The minutes of the last meeting were read and confirmed, and Messrs. A. A. Atkins, S. Baxter, C. J. Jarvis, and R. L. Wareham, were elected members.

The following gentlemen were nominated for election:—Messrs. F. Barnett, H. R. Wakefield, G. Wiseman, E. Shilton, and C. W. Tiern.

A communication was handed in from the Meteorological Society, asking for photographs of lightning from members who had taken or would take some when opportunity occurred.

Mr. J. H. PICKARD read record of excursion to Miller's Dale:—

With a contingent of twelve members and ladies, we started on Whit Monday morning by Midland Railway at nine a.m. After a quick run, we arrived at Miller's Dale Station. The first thing to do was to make tracks for the "Anglers' Rest" Hotel to arrange for our evening repast. Commencing with taking views of the picturesque village and winding river, we then proceeded along the road, above which runs the lofty railway viaduct, finding many points of interest, especially at the mill and bridge, and came to the pass through the Miller's Dale, a short distance bringing us quickly into its beauties. It opens somewhat similar to Dove Dale, a sort of torrent walk giving capital studies for the camera of trees and stream effects. The Dale at the distance of about a mile widens out, with high hills on the one side, the stream or River Wye winding in and out, giving many tempting bits of scenery. We then proceeded to some natural steps in the rocks leading to a fine rocky dell or gorge, which presented a beautiful effect when viewed through the ground-glass, rather difficult to take, owing to the diversity of light and depth of shadow. Turning to the left, and climbing up and down the rocks, slippery with moss, &c., making our way slightly perilous, many of us having awkward slips, we came suddenly upon a grand scene, without doubt the finest of its kind our cameras have been pointed at. "The celebrated Chee Tor," the numberless cascades on the winding river running through the chasm between the gigantic rocks, covered in many places with climbing verdure almost to the top. These rocks are of a horsehoe shape, the deep chasm no doubt having been formed by volcanic action or a mighty rush of water in remote ages ago; in some parts the grandeur is almost appalling. It was in this gorge that our facetious Mr. Cox was infatuated enough to take up his dwelling in a small, narrow cave to have his physiognomy photographed; when it was done he coolly said, "Give the picture a name." Echo answered, "The Cheethal of Chee Tor." The pathway along this gorge is rather dangerous, and in wet weather is impassable owing to the water rising above the narrow pathway under the cavern-like openings under the side of the rocks, in many cases only stepping-stones under dropping wells, the surface-water percolating through the rocks. One might stay here and take pictures by the score, each turn giving you fresh beauties. Crossing the stream by a trellis bridge, and under a wonderful railway bridge thrown across the chasm from the mouth of one tunnel to another. (The chasm and bridges reminded one of the "Devil's Bridge," at Aberystwith.) We could not get a picture of these bridges owing to the foliage being blown about so by wind, which rushes through the opening, and the light preventing us using the shutter. With regret, we followed in single file (the ladies preferring to stay where they were till our return) along the pathway, and, descending by a long length of steps, crossed the stream again, reaching the valley along which the path runs towards Buxton. Some good views were obtained here, but time not allowing us to go farther, we rejoined our companions and retraced our way, photographing whatever points we had missed in the morning. On reaching the railway bridge at the village, passing shots were had at the express train, also a fine flock of geese. The concluding picture was taken by our rear guard, Mr. Iliff, namely, a group, to help to swell our book of excursionists; and, after a capital tea, &c., we reached the station in good time, and arrived in New-street Station about forty minutes past ten p.m., all well pleased and with great intentions to go over the same ground some other time again. The number of pictures taken was one hundred and seven.

The CHAIRMAN gave notice of the Glasgow Convention on July 4 next.

A number of exhibits of photographs taken at the last excursion by Messrs. Birkett, J. H. Pickard, and Humphries, and some very fine instantaneous ones of the new steamers plying to the Isle of Man by Mr. E. H. Jaques, which were much admired.

Mr. F. BIRKETT then gave his paper on *Printing by Artificial Light*. He mainly drew the members' attention to Alpha paper printing, and, in the course of his remarks, said:—

It is an advantage to amateurs on some occasions to be enabled to print from their negatives at night or during the winter months. There are two kinds of papers one can use—the bromide and the chloride. The bromide is pretty well known in the shape of Eastman's, Morgan & Kidd's, Fry's, Marion's, and others; but with all these the black and white tones only can be obtained. Many people say this looks cold; they like something warmer, or more like the tone of the silver prints on albumenized paper. By using the chloride you can get almost any tone you wish. Still, preferring myself the ordinary silver print, I use as a substitute the Alpha paper. I used Morgan & Kidd's contact paper till they discontinued making it. The negative should be a good one, not too thin. On bromide paper a thin negative will give a good print, but with the chloride a plucky negative, as with silver prints, gives the best results. The light through one thickness of golden fabric is quite subdued enough to work by; in fact, I have used the gaslight, turning down just enough to see what I was doing, of course keeping my dishes well covered up as much as possible. Exposure comes next. It is here you must decide what tone you want the resulting prints to be. For a warm tone give a long exposure and short development; for a black tone a short exposure and long development. A long exposure means two minutes, twelve inches from an ordinary gaslight, a dense negative requiring much more. The developer is the one given by the makers of the paper, namely, a weak iron one. Wet the prints in clean water, and place in developer (not too many at once). The picture comes out quickly; you will see how far to go. They will alter but little in tone in the subsequent solutions, &c. Wash at once in a

solution of citric acid made very weak, or it will fetch the picture off; well wash. Tone in acetate toning bath with chloride of lime. You cannot see much change in the colour; for myself I leave them four or five minutes. Fix in the ordinary way; but here they must be carefully watched as they turn a nasty yellow, then brown. The moment they reach the colour you require well wash in several waters. All the waters and solutions must be cold. The face of the print can be glossed or polished by drying on ebonite or glass, cleaned with French chalk.

The paper was accompanied with practical illustrations, and proved very interesting.

The CHAIRMAN asked members to come forward with papers for the remaining half session, some few being required to fill up the programme, and the meeting concluded.

PHOTOGRAPHIC SOCIETY OF PHILADELPHIA.

A STATED meeting of the Society was held Wednesday evening, June 1, with the President, Mr. Frederick Graff, in the chair.

The Committee on Presentation Pictures for 1887 reported that they had selected *On a Virginia Turnpike*, by Mr. John G. Bullock, and *The Elephant's Caves, India*, by Mr. Charles R. Pancoast.

The paper for the evening was read by Mr. CHARLES TRUSCOTT, the subject being *Some Photographic Heresies* [this will appear in a future number]. The reading of the paper was followed by an interesting discussion of various points touched on by the writer.

Mr. COATES preferred to use plates slow enough to give several seconds' exposure, as with extremely rapid plates cap exposures could not well be given for such times as one, one and a half, or one and three-quarter seconds.

Mr. ZECKWER suggested the plan of counting as rapidly as the numbers could be pronounced from one to five, which would be found to take about one second. If, then, one and three-fifths of a second are required for the exposure, by counting thus rapidly one to five and then one to three the fraction of the second would be determined with sufficient accuracy for practical purposes.

It being suggested that the time could be prolonged by use of a small stop, Mr. TRUSCOTT made the objection that this was likely to cause diffraction of the rays of light, and consequent fogging of the plate. He stated that the shutter he used was accurately graded for short time work from one-two-hundred-and-fiftieth to two-thirds of a second.

In reply to a question by Dr. Wallace, Mr. TRUSCOTT stated that in wet plate photography with short time exposures, such as portraits of babies, &c., he had frequently heated the developer to about 100° Fahr. before applying to the plate. For developing short exposures on gelatine plates, he used carbonate of soda, one part to four of water, varying the solution from one-fourth to full strength. He found different brands of plates to vary greatly in the time necessary for development. As to the most desirable position for a shutter, he considered back of the lens the best for avoiding fog, and in the middle of the lens the best for economising space.

Mr. FASSITT called attention to an article on page 144 of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1887, on *A Cheap, Simple, and Effective Reducer for Gelatine Negatives*. The directions called for diluting "ordinary chloride of lime with half its bulk of water," and then immersing the negative in the mixture about twenty seconds. Mr. Fassitt found on trying the plan that the quantities specified produced merely a thick paste, and not a solution in which the plate could be well "immersed." Its action was to quickly and entirely remove every vestige of the film from the plate. As to its effectiveness there could be no doubt, but its use for any other purpose than cleaning glass could hardly be advised. The publication of such impracticable recipes was calculated to do much harm, as they are frequently copied into one journal after another without trial or investigation by the publishers, continuing their misleading career indefinitely.

Adjourned.

Correspondence.

Correspondents should never write on both sides of the paper.

JUBILEE.

To the EDITORS.

GENTLEMEN,—Jubilee Day, the 21st of June, 1887, was twin sister to the first day of Her Most Gracious Majesty's reign in 1837, both unexceptional model days in unclouded sunshine, and the first in the world's history of a Queen's Jubilee. The newspapers have been full of the episodes of the Victorian age, but none has realised it more beautifully than Liverpool, in grouping together life-size marble busts of Her Majesty and her family amidst floral decoration in one of the large halls of the Walker Art Gallery. It is the arrangement of Mr. Charles Dyall, the Curator, whose talents in this peculiar display of art is well known. It has been photographed by Messrs. Brown, Barnes, & Bell, of this city, and makes a very fine *souvenir* of this most interesting event.

It was not until 1839 that the art-science of Photography was discovered; the pencil of light was led captive to delineate everything that is lovely in nature, and has become the handmaid of Art, Science, Commerce, and Manufacture. In its short life it has given lustre and happiness to every cottage, as well as every palace, throughout the world. It has even startled us by its boundless revelations of star worlds, that even the telescope has failed to discover. It has given employment to millions all over the world, and opened the floodgates of art treasures hoarded for centuries to the great masses of all peoples in every land. Thus the seed has been sown that will fructify in ages to come.

I feel compelled to drop the metaphor to return to a record of photography on the Jubilee Day. Alderman Samuelson, who now resides at Trefri, North Wales, invited the photographic societies of this city and Birkenhead. Twenty in number accepted, and a more enjoyable day was

never spent among the beautiful scenery of that charming neighbourhood; 165 plates were exposed, a selection of which are to be presented to Mr. Samuelson as a *souvenir* of the happy Jubilee, which ended in a most hearty singing of the National Anthem.

JAMES ALEX. FORRENT,

President of Birkenhead Photographic Society.

Liverpool, June 29, 1887.

HER MAJESTY'S JUBILEE—PHOTOGRAPHERS' OFFERING.

To the EDITORS.

GENTLEMEN,—May I offer the following suggestion? In every town in the kingdom, and almost every village, some loyal demonstration has been made in honour of our Queen. It has also happened that in nearly every instance the local photographer has secured views of the decorations, processions, triumphal arches, dinner tables, &c. Now these photographs, if collected, would convey more real information than twenty newspaper reports. If you were to solicit from every photographer one or two of his views taken on Jubilee Day (he would be sure to send his best), each mount would bear his name and address, and this might be supplemented by any remarks in pencil at the back. These views could be classified, and either be put in an album or casket and presented to Her Majesty the Queen. This would form a pretty and grateful offering from a large and widely spread body of gentlemen who represent commercial photography to one of its most liberal patrons—the Queen. Leaving the suggestion in your hands—I am, yours, &c.,

42, Northbrook-street, Newbury, Berks.

THOMAS B. HOWZ.

OUR FATHERS: WHERE ARE THEY?

To the EDITORS.

GENTLEMEN,—Being engaged on a large historical work, a portion of which includes the portraits of the most prominent Victorian celebrities, I have been endeavouring, in order to give a place to the wonderful invention and development of photography, to procure portraits of three of the following: Fox Talbot, Mungo Ponton, Woodbury, Herbert Hunt, and Hugh Diamond; but up to the present I have not succeeded in even finding the slightest trace, and, further, in making inquiries at many London and provincial photographers and dealers, a look of conscious innocence illuminated their countenances, and a smile of incredulity overspread their faces on the name of Mungo Ponton being mentioned. "Who was he?" they asked, with a "No you don't" sort of expression, evidently regarding the question as an attempt—to use a rather vulgar expression—to take a rise out of them. That Mungo Ponton's name is apparently unknown, even to photographers, is, perhaps, not to be wondered at, as he was so remotely connected with photography. But still, one would have thought that a remembrance of him who discovered the principle upon which is founded the whole of the art of pigment printing, collotype, and kindred processes, would have lingered in the minds of those who practise photography, but lack, apparently, a true interest in the history of their art. With regard to the other portraits, it is scarcely credible that none are on sale anywhere, nor any information obtainable. In making inquiries I have been passed, battledoor-and-shuttlecock fashion, from one to the other, and am at last compelled to appeal to the readers of THE BRITISH JOURNAL OF PHOTOGRAPHY, who I trust will be able to afford me some information as to where I can procure them. Trusting to be kindly favoured with their valuable assistance—I am, yours, &c.,

Pro CHARLES MASON, G. W. B.

The Studio, George-street, Hull, June 18, 1887.

MEDAL AWARDS.

To the EDITORS.

GENTLEMEN,—Mr. Lydell Sawyer must not be too hasty, there are two other gentlemen who claim to wear the same head-gear. I congratulate Mr. Sawyer upon being one of the first to put his signature below his insinuations; the insinuations themselves, however, are not of much account. It is possible, and very probable, that the gentlemen of whom he writes have as keen a sense of honour as himself.

I notice that Mr. Sawyer does not venture to repudiate my remarks about those members of the photographic body who pose as reformers in public, but who, when in positions where their support and influence would be valuable, are not to be relied on.

The Parent Society's system is (I agree with Mr. Sawyer) a very good one; but I believe that all its exhibitions are followed by growls and grumbings, showing that no matter how perfect the system some one is found to be dissatisfied. Our Society adopted what I think was a very good rule, and an "element of safety," namely, that no "name" was to be permitted on the front of exhibit. This, however, was rescinded at a small meeting held in March, Mr. Sawyer himself seconding the proposition to that effect. Mr. Sawyer also took part in the nomination of Judges.

I don't remember that he raised any objections, or expressed any doubts as to the fitness of the gentlemen nominated.—I am, yours, &c.,

J. PIERCE.

16, New Bridge-street, Newcastle, June 28, 1887.

"SECRET PROCESSES."

To the EDITORS.

GENTLEMEN,—I should have been glad if "Monitor" had passed over the blunder he refers to. What I really said at the meeting of the Manchester Society was that I had always freely given information, the only exception being my process for printing on canvas. This I repeat—I said it without boasting, and it was in reply to remarks which were disparaging to professional photographers. Bad reporting I am not responsible for. I saw the blunder in the JOURNAL, but did not think it worth the trouble of correction.—I am, yours, &c.,
A. BROTHERS.
Manchester, June 25, 1887.

Exchange Column.

Wanted, gem or Victoria lenses in exchange for coloured lantern slides.—Address, R., 8, Cyprus-villas, Garforth.
Wanted, half-plate lens in exchange for good background by Marion or show cases.—Address, A. B., 658, Holloway-road, N.
Dark box on wheels for exchange. Wanted, studio stand or head-rests.—Address, W. 10, Medcalfe-place, Pentonville-road, London.
Will exchange Marion and Seavey backgrounds, &c., for a good light 12x10 camera and slides, or anything useful.—Address, F. WHALER, Lincoln.
For exchange, two sets of gem lenses, twelve on plate, and nine ditto. Wanted, good quarter-plate or cabinet lens by known maker.—Address, W. LEE, Photographer, Llandudno.
I will exchange limelight apparatus, four good sets of slides, popular subjects, for accessories, posing-chair, or whole-plate camera.—Address, T. H. PRICE, Dursley, Gloucestershire.
Will exchange one of Fallowfield's oscillating cabinet burnishers, new, cost 30s., for interior background or rustic accessories.—Address, J. V. VALENTINE, 18, Bank-street, Teignmouth.
I will exchange an enlarging apparatus, seven-inch compound condenser, for a really, good whole-plate camera and three slides for outdoor work.—Address, W. DAKIN, 1, High-street, Sheffield.

Answers to Correspondents.

PHOTOGRAPHS REGISTERED:—

G. Watmough Webster, 33, Bridge-street-row, Chester.—Portrait of "Gamecock" and jockey.
R. M. Campbell, Campbelltown.—Three photographs of obelisk monument to the memory of J. F. Campbell.
James Thomson, 21, High Park-street, Liverpool.—Photograph of the s.s. "City of Rome."
James Bellman, Victoria-road, Whitehaven.—Group of "The Whitehaven screen girls' deputation to the Home Secretary."
D. Bordley, Newport-road, Stafford.—Photograph of W. H. Peach, Esq., Mayor of Stafford.
H. T. Austin, Clifton-villa, Knowle Park, Bristol.—Group of Clergy of Holy Nativity; Portrait of Rev. G. Dunlop.
J. A. Billinger, Sidmouth, Devon.—Three views of Jubilee procession in Sidmouth.

AN EXCHANGER.—If you or other correspondents desiring exchanges are so careless as not to write your names and addresses correctly, that is your affair, not ours.

S. W. A. asks which process will yield the best copy of a Daguerreotype: gelatine or collodion?—The one is as good as the other; it is simply a question of skill.

A TWELVE-YEARS'-OLD CORRESPONDENT.—See Monckhoven's *Treatise on Optics*. Failing that, try *A Treatise on Optics*, published by R. & W. Chambers. See also Brewster's *Optics*.

J. COURTIER.—The probable cause of the veiled appearance of the negatives, after intensifying by the bichloride of mercury and ammonia method, is that the plate was insufficiently washed between the operations.

SALTED PLAIN PAPER.—W. R. Ridgway & Co., Ealing, London, say that with reference to our article on this subject, they have been supplying the same for some time. We refer those of our readers interested to them.

COLLOTYPE.—We have not received the paper referred to. You will find formulae and method of preparing the plates in the last edition of Hardwich's *Photographic Chemistry*. It would take up too much space to give it in this column.

W. WOOD.—1. The proportion of sulphite of soda has nothing to do with the quantity of water but of the pyrogallic acid. To each ounce of pyrogallic from four to six ounces of the sulphite are usually added.—2. Either will answer.—3. No.

C. A.—Your best plan will be to write and complain to the one who supplied the goods to you. It is no use your communicating direct to the manufacturer, even if you know who he is, as you have had no transactions with him—you are not his customer.

E. B.—It is impossible for us to indicate the cause of the spots. They look, however, very much as if they were caused by minute bubbles of air adhering to the surface of the paper while it was in the fixing bath. But we should be sorry to say that they are really due to this. Is the water you are using highly charged with lime?

A.—Those who manufacture the ready sensitised paper do not publish the formulae they employ, but look upon it as a "trade secret." Various formulae have from time to time been published, but, so far as our experience goes, none of them will give results, as regards toning and keeping qualities, equal to the best papers met with in commerce.

A. PARKER.—From this correspondent we have received a couple of prints on opal glass, and he wishes to know the reason they are of such a cold tone, while those supplied by professional enlargers are much warmer.—The reason of the coldness of tone is due to the pictures being under exposed and too much forced in the development. The remedy is obvious.

W. B. CASSINGHAM writes: "Are dry plates thickly coated better than thin ones? If so, what are the advantages of thickly coated ones? An answer will oblige."—Plates rich in bromide of silver are better than those which are but thinly coated, as they give a more "plucky" picture and are freer from halation. Beyond a certain point, however, no advantage is gained by an extra thick coating.

LEONOR STEINER writes: "I have been trying to colour some photographs for enamelling, using oil colours with a little turps, but to my great disappointment, when they have been enamelled, enamel and colour both peel off. Will you therefore tell me what I should do to prevent it?"—Perhaps some of our readers who have had experience in this direction will supply the desired information.

T. EVANS sends us some specimens of enlargements on gelatino-bromide paper which he has made, and asks the cause of their weak and fogged appearance, as he has kept strictly to the formula issued by the Eastman Company.—The cause of failure arises from over exposure. In his next essay our correspondent should try half the time previously given, with the same negatives. If with this exposure he does not obtain sufficient vigour he must try still less.

ELEN.—The thinness of the negative is due to its being very much over exposed. About a fourth the time, or even less, than that you gave would have been sufficient. Your best plan will be to take the subject again; next to that we should advise you to make a transparency, and from that make a fresh negative, exaggerating the contrasts in each operation. The negative is too much over exposed to make anything good of it by any method of intensification.

S. S.—We have not tried the material mentioned, so cannot give an opinion as to its merits. The common gilt frames are not prepared with bronze powder, so that there is no fear that any will become detached and eventually injure the photographs. If the "washing" is simply the water in which the prints are washed prior to toning, common salt will precipitate the silver as a chloride. But if they contain hyposulphite of soda, sulphide of potassium (liver of sulphur) must be employed.

H. R. H. says: "1. I have a tub which I got from a grocer (i.e. a salt butter tub), which I wish to use for washing negatives. I find I cannot get rid of the salt which the butter has left in the wood. Will it injure the negatives if the washing water contains a trace of the said salt? 2. Can photographs be taken in the streets of London without fear of one being moved on by the man in blue?—3. I have a plate box which has been varnished inside with spirit varnish: is it injurious to dry plates? It smells strong of the varnish.—1. The salt can all be removed by long soaking in water. A minute trace of the salt such as would remain after this treatment will do no harm.—2. Unless an obstruction to the traffic is caused, the police will not interfere.—3. If the box be left open in the sun for a time the smell of the spirit will fly off.

T. B. LATCHMORE writes as follows: "Observing in the *Standard* yesterday (June 23) an account of a disastrous fire which broke out at Messrs. Dale & Co.'s chemical works, and which was attributed to an explosion of a quantity of bichromate of potash, I must say that I was not at all aware that the chemical in question was of such a dangerous nature as to be liable to explode and cause so much damage to life and property. Is there not some error in the printing? If not, we photographers must be careful as to the quantity and storing of bichromate of potash."—In reply: The daily papers appear to have got considerably "mixed" over this affair. Some have attributed the catastrophe to one thing and some to another. At present the cause is a mystery, which will probably be solved at the inquest. One thing is certain, namely, that bichromate of potash is not an explosive salt, although some of the potash salts are, the picrate for example.

RECEIVED.—"More Light;" Price List of Cameras, Lenses, and Apparatus, by George Houghton & Son.

NORTH LONDON PHOTOGRAPHIC SOCIETY.—There will be an excursion to Shepperton on Saturday, July 2. The train leaves Waterloo at thirty-five minutes past two p.m.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, July 6, 1887, will be on *Actinometers*. Saturday outing at Shepperton. Train from Waterloo at thirty-five minutes past two.

LONDON STEREOSCOPIC COMPANY'S EXHIBITION.—The Secretary of this Company desires us to notify the fact that Captain Abney is to be one of the judges at their forthcoming exhibition. He says further that the Company will be glad to send to applicants the rules and regulations concerning this competition.

On Friday, June 24, Barnet was favoured by a visit from a very charming specimen of Royalty in the person of the Princess Feodora, the eldest of the Queen's great-grandchildren, the young Princess making a short stay at Hadley Hurst, the residence of Wilbraham Taylor, where the planting of a tree took place, and some excellent photographs were taken of this charming little Princess by Alfred Alonzo Ferrari, of the Art Studio, High Barnet.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1418. VOL. XXXIV.—JULY 8, 1887.

TONING GELATINO-CHLORIDE PRINTS WITH SEL D'OR.

SOME recent experiments in toning with the preparation formerly sold under the name of *sel d'or*, are strongly suggestive of the existence of a greater difference between the images produced upon gelatino-chloride and albumen papers respectively than we are in the habit of suspecting.

As is well known to all who have employed gelatino-chloride paper, a special toning bath is necessary, or, at least, it is requisite to compound a solution differing entirely, both in strength and composition, from that employed for albumenised paper. The ordinary alkaline bath in everyday use produces not the slightest toning effect upon the new paper, unless it be left for such a prolonged period that the lights become hopelessly discoloured. It is only when the proportion of gold is vastly increased—one grain of the salt to two or two and a half ounces of water—that toning proceeds with anything like celerity; but the best results are not gained until a considerable quantity of a soluble sulphocyanide—and, in some cases, a trace of our old enemy, “hypo”—are added to the bath. In fact, gelatino-chloride paper appears to work better under conditions approaching those of sulphur toning.

Such being the case, it is scarcely surprising that when, a few days ago, we fell across a small capsuled, stoppered bottle of *sel d'or*, the idea should strike us to try it upon the new paper. Despite its great antiquity—the preparation was of the well-known Fordos & Gelis brand, and must have been a quarter of a century old—the salt appeared to be in perfectly good condition. It was made up into a toning bath by dissolving the contents of the bottle (one gramme) in thirty ounces of water, and rendering the solution faintly acid with hydrochloric acid. In adopting these proportions, we may add we worked entirely from memory.

Several prints upon gelatino-chloride paper, as well as two or three upon ordinary ready-sensitised albumen paper for comparison, were thoroughly washed and treated with chloride of sodium, in order to remove every trace of free silver. Upon immersion in the *sel d'or* bath, the gelatino-chloride prints commenced to change colour in two or three minutes, and then, proceeding rapidly, were fully toned to a rich purple-black in about five or six minutes. The albumen prints, however, refused to tone at all, and even after sixteen hours immersion had not changed colour in the slightest degree.

We were quite unprepared for the latter result, though by no means surprised at the difference of behaviour between the two kinds of paper, for in previous experiments we have frequently found not only that an alkaline bath which will colour an albumen print rapidly will produce no effect whatever on a

gelatino picture, but that a solution which is strong enough in gold to act energetically upon gelatine will have little or no action on the other. In fact, acidity or the absence of alkalinity of the bath appears to favour toning in the case of gelatino paper, and the reverse in the case of albumen.

But to return to our toned prints. These, after removal from the bath of *sel d'or* were placed to soak in clean water. Be it noted here that there was no chance of free silver being present at any stage to account for the result we are about to record. To obviate the possibility of the formation of hyposulphite of silver by the action of the *sel d'or*, the prints were treated as we have stated, with salt, in order to convert any free silver, and fresh water was employed at every stage.

When the prints left the toning bath, their appearance was in every way satisfactory, the tone possessing that velvety purple character so well known in connection with gelatino-chloride at this stage, while the lights were perfectly bright and pure. On turning them over, however, after a few minutes' soaking, we were horrified to find them, without exception, changed to a deep, dirty yellow, highly suggestive of sulphuration in its worst form, and of just such a degree and character as might be anticipated if a print containing free silver were placed direct into the hypo bath without previous washing.

The albumen prints, it may be here stated, were entirely unaffected in this manner, the whites remaining as pure after several hours' immersion, and also after washing, as at first, the toning bath, in fact, apparently exercising not the slightest action of any sort.

Cogitating on the matter, we remembered that the addition of hydrochloric acid was made to the bath in former days for the express purpose of avoiding a similar yellow stain, but we could not recollect the exact proportions. We had employed just sufficient to turn the scale of neutrality, and this probably was not sufficient. Upon turning up an old formula we found that our proportions of gold salt and of water were correct, but that one *drachm* of pure hydrochloric acid should have been used instead of, probably, one *minim*.

The correction was made, and a fresh batch of prints were toned, being subjected to the same precautionary treatment as previously to guard against free silver. The toning proceeded as satisfactorily in every way, and the final result was precisely similar to that already described—hopeless discolouration, commencing in one or two instances in this batch of prints in the toning bath itself. The yellow colour, moreover, was found to deepen considerably when the prints went into the fixing bath of fresh hypo.

In the second or more acid bath albumenised paper prints were equally unaffected both as regards toning and sulphura-

tion, and it is this marked difference in behaviour which causes us to question whether there may not be a greater difference in the constitution of the gelatino-chloride film, as compared with albumen, than we have hitherto supposed. The yellow stain is quite invisible from the *back* of the print, and is, indeed, found to be confined simply to the gelatine itself, since, if the latter be dissolved off with warm water, the paper is left perfectly white.

A possible explanation suggests itself to us, namely, that the contact of free silver with the gelatine, in making the emulsion, forms an organic compound which is acted upon—sulphurised, in fact—by the *sel d'or*. If this be so, it is a strong impeachment against gelatine as the basis of printing surfaces—at least, where it is necessary to employ free silver, as for papers for “printing-out.” We have not yet submitted the prints to any tests, but shall shortly do so.

THE RIGHT TO THE NEGATIVE.

THE letter of Mr. Arthur Debenham, which appeared in our columns some time since, has given rise to a large amount of correspondence with reference to the sitter's alleged right to the negative. Some of the writers have expressed a very decided opinion, because a higher charge is made for the first supply of portraits than for subsequent copies, that, consequently, the negative is the property of the sitter. Others, on the contrary, consider, according to the usage of business, it belongs to the photographer. Many of the arguments adduced, and analogies quoted, have scarcely been to the point, as they have had no bearing on photography or the established custom of photographers. It is tolerably well known in Courts of Law, that in any disputed point a well-recognised rule or custom in any particular trade or business transactions is looked upon as being nearly, if not quite, equivalent to law itself.

It is a very common circumstance, whenever the question as to the proprietorship of the negative is under discussion, to quote the case of an engraved plate. In the case of works of art the simile certainly does not apply to photography at all, inasmuch as the engraver's is a separate business, and so is the printer's. The former engraves the plate, but does not supply impressions therefrom. In the case of address or business cards it is somewhat different, but here a definite charge is made for engraving the plate; or sometimes the agreement is for a card plate and so many cards for a certain sum. In any case the custom of the trade is that the plate for which a specific charge has been made is the property of the customer. But when a similar order is executed from type, the “forme” does not become his property, although a proportionately much higher charge, to cover the cost of setting up, is made for fifty than for five hundred or a thousand impressions. It has been argued, because the forme can be broken up, and the type used for other purposes, and the plate is useless except to the customer, that the latter should be his property and the former not. To meet this, opponents have argued that the engraving can be removed and the copper re-engraved. Also that the negative can be cleaned off, and the glass and silver utilised, like the type, for another purpose. This is simply special pleading, and has no legal value whatever.

Let us now turn to the business part of the question, and see what has always been the custom of the trade as regards negatives taken in the ordinary course, and also what has legally been decided with reference to their ownership. Going

back to the Talbotype days, when one or two portraits were about as many as were ever ordered at a time, the negative always remained the property of the photographer.

In the days of the collodion process we find the negative recognised as belonging to the photographer. In the very early period of that era it was usual to have on the printed receipt for payment for sittings an announcement something like the following:—The negative will be retained for twelve months—or other time—during which period copies can be had for so much, usually half price. Here is tacit understanding that the sitter had no title to the negative. One firm we have in our mind just now, who had several establishments in London as well as in the provinces some thirty years or so ago, used to have a paragraph in their prospectus stating that the negative would be kept for a certain number of months, during which time duplicates could be obtained at such and such a sum, or the negative might be purchased for half the price charged for the first portrait. Here again is a distinct understanding that the negative belonged to the artist, and could only become the property of the sitter by purchase.

Later on, when the *carte-de-visite* came into vogue, and portraits were ordered by the dozen instead of singly, we find the custom then was not to destroy the negative at the end of a given period, but to keep it indefinitely; hence the intimation on the backs of the mounts, “The negative of this portrait is preserved, and copies may be obtained at any time by quoting the number.” How could copies be supplied if the negative were not the property of the photographer? Here is another proof of the recognition that the right to the negative belongs to the photographer. Mr. Silvy, when he retired from business in this country, advertised in the daily papers that any of the negatives he had taken could be purchased by the sitters for a certain sum, and that any photographer could print therefrom. As a matter of fact, the sitter bargains and pays only for portraits, and not for portraits and the negative from which they are made; and the custom of the trade is, and always has been, that he is in no way entitled to it except by special agreement.

Evidently the title of photographers to the negative is recognised by the framers of the later projected copyright bills, who, by the way, are not supposed to be particularly favourably inclined towards the craft. One of the clauses stipulates, that when a portrait is taken for a valuable consideration the photographer must not use the negative for any purpose of his own, or make copies therefrom, except to the order of the sitter. Here, by implication, the negative is admitted to belong to the photographer.

Having considered the question from the “custom of trade,” or unwritten law, point of view, let us now turn to what has already been legally decided on the point. In 1880, Mr. Dixon, of Albany-street, sued a pianoforte-maker in the County Court for the sum of four pounds for two proofs and the negative itself of a pianoforte he had photographed. The claim was resisted on the ground that the negative should not be charged for. The Judge, however, was of a different opinion, and said that “the defence set up could not be maintained, for the negative of a picture was the most valuable property in it, as by it the defendant could have copies printed by another photographer elsewhere.” Judgment was accordingly entered for the plaintiff for the full amount claimed. Clearly, in this case the negative belonged to the photographer by right, otherwise he could not have recovered its value.

Here is another case in which the right to a portrait nega-

tive was contested, and the decision leaves no doubt on the point. The case was tried in the Bloomsbury County Court in 1876, and will be found reported on page 359 of our volume for that year. Briefly the case was this: The plaintiff, a photographer, sued the defendant for thirty shillings, the price of a dozen cabinet portraits of his wife, which had been duly supplied and approved of. Here is the defence and judgment.

"The defendant did not deny the order being given, nor that the charge made was a reasonable one, but declined payment on the ground that the order had not been completed, inasmuch as the price charged included the purchase of the negative, from which, as he was going to India, he might get additional copies printed if he required: moreover, the defendant said he strongly objected to leaving the negative in the possession of the plaintiff, as he had no wish to see his wife's portrait exhibited amongst the plaintiff's specimens, which photographers were in the habit of doing when they took an attractive picture. The defendant's wife was called, who corroborated her husband's statement. The plaintiff, being recalled, stated that the purchase of the negative was never mentioned, and that it was always customary to keep negative unless some special arrangement was come to for its delivery to the sitter. The Judge considered that no respectable photographers would exhibit their clients' portraits without permission being obtained, and, as the present defendant had not proved the purchase of the negative, judgment would be in favour of the plaintiff for the full amount claimed, with costs of two witnesses."

Although the above are only County Court judgments, they stand as a precept until they are overruled by a reverse decision in one of the superior courts.

RESPECTING the Photographic Convention, a writer in the *Scottish News* remarks:—"Unostentatiously enough, but with all heartiness and cordiality, the Photographic Convention was opened last night in Glasgow. In its own way, the Convention—the second of its kind—is of considerable importance. From all parts of the country, some two hundred practical photographers have come together to discuss subjects in connection with the art of photography—an art whose progress can only be compared to that of the appliances of steam for practical purposes, or that of the mysteries of electricity. Half a century ago photography was in a very crude and primitive condition, but it has advanced with the times, and now it ranks next in beauty and importance to the divine art of painting itself. A Convention such as that which opened its proceedings last night in Glasgow is not likely to pass away without good results where there is such a combination and diversity of talent and ingenuity. Besides, it is well that there should be a recognition of the kinship betwixt those that are kin. The Convention in Glasgow will also have this advantage to strangers: its proceedings and the incidental excursions into the picturesque classic districts with which the country abounds, will give them a glimpse of certain beauties of nature hitherto, perhaps, unknown to them, and which their art will enable them to perpetuate."

ELECTRIC lighting is, perhaps, about the last thing in the mind of the average photographer at this period of the year; but as there are some establishments where it is *de rigueur* all the year round, we need not forbear from echoing the wail of several owners of studios, which has been very common for the last few weeks. "We are simply baked, sirs; if we could only get electricity at a reasonable figure we would shut up our studio and take portraits in a cellar." And, of a truth, the "electrical photographer" has a very strong pull against his daylight brethren of the camera in the matter of weather. In summer there need be no more heat than in an ordinary drawing-room, in winter the effect of a foggy atmosphere is greatly minimised, while all the year round he always has a sufficiency of illumination, whatever the meteorological conditions that may prevail.

Apocryphal of electricity, a very singular danger may be noted. We have heard of serious accidents to the person through electricity, and its possible danger to buildings has long been recognised; but that

there was danger in an incandescent lamp was a thought that would have occurred to few. The well-known electrician, Mr. W. H. Preece, however, calls attention to such a danger, and describes the actual occurrence (an account of which he had received from a correspondent) of an accident caused by the bursting of a 50 c.p. lamp the moment it was connected up for the first time, the glass breaking in his face and filling his eyes with glass dust. Mr. Preece offers as an explanation that there was a slight air leakage in the glass, and a consequent formation of an explosive compound with the residuum of hydrocarbon gas used in exhausting.

It might have been anticipated that the failure of the radiometer to effect a practical service in photography was complete and final, but our contemporary, *La Nature*, which often devotes a considerable portion of its space to matters photographic, has lately resuscitated and republished a paper by M. Olivier presented to the Academy two years ago on the subject of measuring the chemical action of radiations. The plan consists, in brief, of surrounding a radiometer with screens permitting only the chemical rays to pass, placing the instrument so screened in front of the camera, and counting the revolutions made during a correct exposure. M. Olivier states that a similar number of revolutions on any other occasion will, whatever the light, indicate an equivalent exposure, provided the same kind of plate be used. He quite ignores the possibility, not to say the probability, of the light from the sky facing the radiometer being very different from that facing the object photographed. The editor of *La Nature* further points out that the time when the sun is near the zenith is most suitable for employing this modified instrument. Be the value of these objections what it may, we read, nevertheless, that a special radiometer for photographic use is made by Mr. Leguy, and that since the publication of M. Olivier's method upwards of three hundred photographers have adopted it for measuring exposures.

It is often said that the time is long gone by when a pure white sky was considered a most desirable and excellent achievement in a photographic landscape; but in the introduction of clouds there is yet much room for improvement, and the employment of dry plates, which so often permit of the production of clouds and landscape at one exposure, is by no means an unalloyed benefit. It rarely happens that the printing value of sky and landscape on one negative is equal, and the consequence is the production of a sky which, though a vast improvement upon pure white, is still a long way from nature. The use of special negatives for printing-in skies should not be permitted to fall into desuetude, and we would strongly advise every photographer to become possessed of a few "practical" clouds. There need be the less fear of their representing facts falsely, whatever distance apart the cloud and the landscape negatives may have been originally obtained, seeing that, in papers recently read before the English and Scottish Meteorological Societies by the Hon. R. Abercromby, the forms of clouds are shown to be identical in all parts of the world.

Of the many treatises upon the subject of Light, technically or popularly treated, now before the public, one of the most attractive of the latter class is the series of Burnett Lectures upon Light by Professor Stokes, the last of which has been given, and is recently published in book form by Messrs. Macmillan. It treats of many topics interesting to the scientific photographer in a most pleasantly instructive manner. The subject of the photo-chemical theory of the action of light upon the eye, including an excellent, if brief, description of the visual-purple theory, may be particularly noticed; and, indeed, the whole lecture (III.) in which these subjects are treated is well worthy of perusal by all photographers.

We have more than once, when alluding to thermometrical observations, called attention to the liability to incorrect readings through the use of imperfectly graduated instruments, or such as had undergone some change, or possibly, molecular alteration. In many photographic operations a difference of a degree or two is of little moment; but when important processes are described the otherwise useful data are apt to be of little value if temperature observations are recorded, and the instrument employed has not been compared with some standard

thermometer. Let us take, for example, the manufacture of pyroxyline—a difference of two or three degrees in the temperature of the mixed acids is capable of materially altering the properties of the resulting product; and many similar cases could be instanced. Of the extent to which thermometers may mislead, when in the hands even of professed observers, an extraordinary instance has recently been given by the newly appointed Government Meteorologist of Queensland, Mr. Clement L. Wragge. In making a round of inspection, this officer discovered at Cooktown—a station of the first class—a spirit thermometer which, owing to the volatilisation of the spirit, had the enormous error of fifteen degrees! It may here be noted that, as many self-registering minimum thermometers are alcoholic and placed in a horizontal position, it is always necessary to observe, when taking a reading, whether there be any spirit in the upper part of the tube, which is very commonly found to be the case.

WE think our readers will be surprised to learn that “Cameras without lenses are becoming quite common in France, especially among amateurs and tourists.” It goes without saying that it is an advantage to the photographer that there is “no outlay for a lens and no fear of breaking it or the ground-glass, which is discarded as well.” But that, “independently of those considerations, photographs of objects can be readily obtained which few lenses would take in,” that “they can, moreover, be taken more accurately,” will, we imagine, intensify the feeling of surprise which any of our readers will experience who saw the above statements in the *English Mechanic* for the 1st of July.

THE PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.

THOSE who hazarded the opinion, or indulged in the hope, that the Glasgow meeting of the Photographic National Convention was to prove a success, have certainly not been disappointed. The local enthusiasm is unbounded; the energy displayed unprecedented in the, as yet, brief history of photography. The pictorial display on the walls of the Institute of the Fine Arts are unmistakably more attractive than anything we have yet seen on those of the Gallery in Pall Mall during the Exhibition of the Photographic Society of Great Britain, while as to the Apparatus Department of the Convention, we venture to state that, both as regards quantity and quality, the Glasgow exhibit stands altogether unrivalled. From north, south, east, and west, the members are, at the time of our writing, pouring in, among them being several ladies. The number of papers contributed up till Monday midday reached the goodly number of *eighteen*, and still more are expected.

In these Art Galleries where the meetings are held, are comprised everything that could conduce either to comfort in the public meetings or the display of pictures and apparatus, together with suites of rooms specially devoted to ladies, smoking room for gentlemen, and writing rooms for those who have occasion to make use of them. So far as we have seen up to the despatching of this article, London is well represented; Birmingham, Derby, Manchester, Dundee, Wick, Kirkwall, Belfast, Dublin, are also all represented. Glasgow and its suburbs, as might be expected, are in strong force. The adjoining city of Edinburgh does not yet appear to have been pervaded by the enthusiasm which otherwise universally prevails to the extent anticipated, which is to be regretted, because that quiescent city of law and learning musters among its citizens several good men. We have, however, recognised at least two members of the Society present.

On Monday evening, at six o'clock, there was a meeting of the General Council, at which the details of the Convention proceedings were arranged. At eight o'clock the proceedings were formally opened.

A few minutes before eight the hall was filled with a large number of ladies and gentlemen, and the chair was taken by Bailie Crawford, who expressed regret that the Lord Provost, Sir James King, who was to have inaugurated the proceedings, could not attend. He, along with Lady King, was in London, assisting at the important function of laying the foundation stone of the Imperial

Institute, a function from which he could not absent himself, being a member of the organizing committee. His lordship, however, had written to him, charging him to welcome the members of the Convention to Glasgow in the name of the citizens, and in his own, and to hope that the important meeting which they were holding here would be a very pleasant and a very profitable one, and that at the end of it they would have no reason to regret having chosen Glasgow as the place in which to hold their second Convention. (Applause.) He understood that the Convention was composed of amateurs and professionals—those who were engaged in photography, and those who had an interest in it—throughout the United Kingdom, and that their object in meeting was to exchange notes, relate experiences, and discuss the later and more difficult points in connection with that most progressive of all arts and industries—photography. Looking at the programme, and seeing that it consisted mostly of excursions to some of the most delightful places in the West of Scotland, he began to wonder where they did their business. However, although it might seem that a considerable portion of their time would be spent, during the week, in what might be called pleasure, he, for one, was of the opinion that that particular part of the proceedings would not be the least valuable to the members. Indeed, he thought the moving about of members amongst each other, taking opportunities for exchanging ideas, for private talk, for comparing experiences, and for getting thoroughly acquainted with each other, would perhaps ultimately be the most beneficial part of the whole proceedings. (Applause.) Photography was not altogether lost sight of in Glasgow. He did not know how it might compare with other places in this respect, but to judge from the amount of rivalry—friendly rivalry, he hoped—which he saw around him among photographers, and the interest taken in it by amateurs, he imagined that Glasgow was entitled to hold a very fair position in the photographic world. (Hear, hear.) He was glad to see that the Convention had been able to organize a most interesting, instructive, and complete exhibition. In the International Exhibition of 1888 at Glasgow, the Fine Art Committee had decided to have a separate section, but in connection with the Fine Art Department, for photography alone—(applause)—and in that section they proposed to deal with photography from its purely artistic point of view, not touching at all on the various methods of production, on the apparatus, or on the chemicals used. As Mr. Lang was the convener of that Committee—a man full of energy and resource—and as he would be assisted by a number of other gentlemen in Glasgow who were thoroughly qualified, and who no doubt would receive the co-operation of others throughout the United Kingdom, he looked forward to the Exhibition being a triumph for the photographic art. (Applause.)

Mr. J. Traill Taylor, Chairman of the Council, remarked that how wisely and how well the Convention had acted in selecting Glasgow for their meeting this year, was amply demonstrated by the success which had attended it. He then announced that up to the present he had received notice of eighteen papers on technical subjects which were to be submitted to the Convention. They were on very varied subjects, ranging from experimenting to copyright, and from home portraiture to the latest methods of taking portraits in natural colours, real or pretended. (Laughter.)

On the motion of Mr. Lang, seconded by Mr. Briginshaw, a hearty vote of thanks was awarded to Bailie Crawford for his conduct in the chair. The Chairman acknowledged the compliment, and afterwards declared the Convention opened for business.

The room was then darkened, and a variety of views were exhibited by means of the lantern, Mr. Pringle describing them in his usual racy manner. The views consisted chiefly of the parts of the country to be visited by the members of the Convention. There were a number of excellent views on the Clyde, with shipping, by Mr. Armstrong, and a number from the Trossachs by the same gentleman and by Mr. Watson. Some beautiful microscopic slides and scenery, taken by Mr. Pringle and also by Mr. Wellington mostly during last year's Convention, were likewise exhibited. The whole exhibition—a most interesting one throughout—concluded with a display of microscopic objects taken by polarised light by Mr. Briginshaw.

Before the proceedings were terminated, the arrival of the evening trains from the South brought a considerable accession to the numerical strength of the Convention, among the late arrivals being Professor

Herschel, F.R.S., President of the Newcastle-on-Tyne Photographic Association.

On Tuesday there were two excursions, one to the Falls of Clyde, under the conductorship of Mr. George Bell, the other to the Trossachs and Loch Katrine, Mr. T. N. Armstrong acting as conductor. A large party went to the former place, where, notwithstanding a severe thunderstorm which was experienced, numerous negatives were taken. But the locality which proved to possess most attraction for the majority of the Convention was the Trossachs and the adjoining Loch Katrine. But as our Special Correspondent was making notes of the various incidents which occurred on this department of the excursion, he will doubtless have something to say concerning it in another number; suffice it for the present to say that the rugged pass of the Trossachs was never before invaded by such an army of "camera men" as on Tuesday.

The ladies of the party having been left at the boathouse at the head of the loch, the dark and, in a former period, deathly and dangerous defile was re-entered. By the thoughtful care of our guide numerous tit-bits of glorious scenery never dreamt of by the ordinary tourist were pointed out, and at certain places something like fifty or sixty cameras of every conceivable form and dimensions were to be seen directed towards mountain, torrents, waterfalls, ravines, and rocky defiles, never before laid under such artistic contribution. Nature was at her very best for the photographic capture of such scenery. A little later the invaders had taken possession of the upper end of the sinuous Loch Katrine, and artistic toll was levied to a fearful extent on its mountainous and lovely banks.

In the evening there was assembled a large audience to hear the reading of papers. This meeting was presided over by Mr. John Stuart, who had only that morning arrived from a visit to Norway. As President of the Glasgow Photographic Society he, in the name of the local photographers, endorsed the welcome that on the previous evening had been extended to the visitors by Bailie Crawford, acting for the Lord Provost. They had all tried their best to make things comfortable and pleasant for their visitors. How far they had succeeded it was not for him to say. The following papers were then read:—

FINDERS AND FOCUSERS.

By LYONEL CLARK, C.E.

COULD one have known Daguerre's thoughts whilst he was sitting with whitewashed face before his camera, patiently waiting for the sluggish plate to delineate his features, we should doubtless have found that he was building aerial castles where exposure was reduced to a minimum, and, indeed, we know how hard he and his successor, Dr. Victor, worked in the direction of improving the rapidity of their sensitive plates. In fact, ever since the discovery of photography, experimenters have been striving to improve in this direction, and there are few commercial brands of plates now made but that are too rapid on open subjects for hand exposure, and some form of shutter is a *sine qua non* with all photographers. But remembering the old adage, although it is an easy thing to get shutters and plates for the most instantaneous kind of work, it is not quite so easy to catch your object. By the time you have focussed and got your back in, slide removed, and shutter set, your subject may be a long way off. In the case of a passing express, the 4.5 problem of Euclid for the tyro amateur, it is easy enough, you can do all that beforehand and await the arrival of the fiery Pegasus, but all animate or moving objects do not run on rails, but have to be followed and taken at any moment. Even at the Zoo, where the denizens are decidedly limited as to recreation ground, it is a constant enough fact to find, after the plate is developed, that the animal is not in focus, or else his tail or head are wanting. In the case of ships and yachts, how often do we see a good picture spoilt owing to the want of a few feet more bowsprit or the peak of the topsail. Of course, with any of the ordinary finders, this should not happen, and as yachts are virtually all taken at about the same distance, the focus does not come in as a factor, for a fixed focus and a small stop brings everything sharp. But in the case of animals, where, perhaps, a portrait lens with small depth of focus must be used, and where the subject is well within the focal variation of the lens, this plan does not work.

Some cameras are marked for foci of varying distances, but this is open to many objections. You have first to train yourself to properly judge the distance, and then you have to rapidly change the eye from the finder to the marks and back again, and it is more by good luck than by skill that you get a successful picture. Men like Mr. Dixon, who

make a speciality of animals, have boldly gone in for double cameras and double lenses, and this plan is without doubt the most effective; but it is expensive and extremely cumbersome, and quite prohibits its general use, for no one could make a point of carrying about two cameras because he might get some instantaneous work. Some time back I tried using a telescope, and marked off the focal lengths to correspond with similar marks on the baseboard of my camera, but soon dropped it, as I found it very inconvenient and required two persons to use it properly. Later on I utilised for the same purpose that scientific toy called the walking-stick telescope. This, as many of you doubtless know, consists of an objective which is clipped on to the walking stick, and can be slid up and down on it, and a plano-concave eye-piece, also fastened on to the stick, thus forming a Galilean or opera-glass style of telescope, and is really of more or less practical use. I screwed an objective of the same focal length as my lens on to the front of my camera, on the back or sliding portion I fixed an ordinary focussing glass with a piece of ground-glass cemented on; subsequently I discarded the ground-glass and substituted a small wire to focus on. This apparatus was adjusted to the camera, and, of course, the two objectives being of the same focal length, when the top one was in focus, the bottom one, that is, the camera proper, was also in focus, and this held good for every position of the object. There was, I believe, nothing new in this. Mr. Traill Taylor described such a focuser at the Conference last year, and Mr. McKellen also made a similar one, and, moreover, I believe it has been described at a much earlier date. The drawback I found was that it only gave you a very small portion of the subject, and you were obliged to have a finder at the same time, and the changing from one to the other I found by no means easy to manage.

Last summer I was rigging up a camera specially to take some puppies and kittens, and had intended rigging up a second camera on top of the first. On working out the designs, I at once saw that by far the simplest and easiest method was to utilise the ground-glass of the camera proper, since it could not be required at the time of exposure. I simply turned up the screen then till it stood vertically above the top of the camera, and in a plane of course parallel to the plane of its usual position. On the front of the camera I raised up an extra front above the existing one, and fitted into it a lens of the same focal length as my objective; this lens was in a sliding tube. I now had the framework of a second camera on top of my first one, and throwing a focussing cloth over the whole, I got an image on my upturned focussing screen. To adjust this, I first focussed very accurately the bottom camera, the screen for this purpose being of course turned down on some object. I then, without shifting the camera, turned the screen up, and clamped it there with some brass pieces, and then slid the tube of the upper lens in and out till I got the same object sharply focussed on the screen in its upper position. Now the two cameras, or rather camera and finder, coincide, and of course as I rack out the one the other follows; and the foci of the two lenses being equal, whenever an object is sharp on the turned up screen I know that it is also sharp on the plate with double back below. There is no need to be particular as to the lens used for the finder—even a spectacle lens will do; but this is objectionable where your lens proper is of a longish focal length, as the spectacle glass is totally uncorrected for spherical aberration, and gives a more or less sharp image over a great depth of focus; a single landscape lens, but with the stops removed to give as much light as possible, is undoubtedly the best, except you go to the expense of having twin lenses.

Although the focussing cloth does extremely well as a makeshift, yet in the ease of wind something more is required. I have a sort of cardboard body, that folds like one of Ottewill's old collapsing cameras. This is made in the form of a truncated pyramid, it slips with an elastic band over the tube of the finder lens, and so gives the play required, the other end comes over the focussing screen and projects like a box a little way beyond it, and gives the necessary shade to it, so as to allow the image to be seen. Many other ways of covering in the finder will doubtless present themselves to you—a body like a Chinese lantern would do, or even an old bellows, though somewhat more bulky; for you must remember that it is not at all necessary to keep out all light, indeed it is surprising how much you can see with nothing between the eye and the ground-glass.

As to the manner of retaining the screen in its upright position or of fixing on the false front, it is impossible to give any strict directions, cameras differ so in construction, but it requires but a small amount of ingenuity to devise some method. I may add that I have for my small camera a focussing eye-piece which is kept pressed up against the ground-glass, being held in position by a spring; this leaves me both hands free to hold the camera and focus, &c., and at the same time permits me of getting, if necessary, a most absolute focus. I have found this little arrangement of focuser and finder, which I described and showed at a meeting of the Camera Club last October, of the very greatest use and benefit. I always carry it about with me, for it at least has the merit of neither adding anything to the bulk or weight of your kit, although at the same time you have all the advantages of a double camera.

Mr. S. D. McKellen said that anterior to Mr. Clark's having submitted this method of focussing to the Camera Club, he, the speaker, had obtained a patent for a system of focussing in which was embraced that now described.

CONCERNING STEREOSCOPIC PICTURES.

By W. M. ASHMAN.

THE renewed interest evinced of late in methods of procuring stereoscopic rotundity in photographic presentments, appears to the writer likely to prove of such beneficial importance to professional workers and dealers in the material used, that reference to the subject will not, I feel sure, be altogether out of place among the topics ranged for profitable discussion at the Convention meetings.

That photographers who depend for sustenance upon their financial successes in the practice of the art have suffered severely from the general depression—and possibly other causes—is now an open secret, and if the signs of recovery are not entirely wanting they are at any rate a trifle obscure and undecided in their character. The best, or an effective, method of circumventing the machinations of the enemy whose identity is so difficult to trace, is the problem which a good sprinkling of the population (photographic) would like to solve.

Doubtless the section of photographers whose interests have been unintentionally imported into these jottings will be supported by abler exponents than myself. I therefore refrain from further remarks in that direction, and pursue the theme which possesses the possibilities of a successful future.

Perhaps some members of the Convention now present have had a large experience in the commercial production of stereoscopic photographs, especially as far back as in the fifties and early part of the sixties, and these gentlemen might possibly add the valuable hints gained in their practical acquaintance with the work to the volume of information disclosed by our good friend Taylor in the last BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, then we may see the stereoscope in every household long before the nineties are reached. Of this I feel confident, that if such additions are not made to the knowledge already so freely distributed, then it must be assumed that there is nothing further to be said about the matter.

There is one point which has impressed itself upon the writer rather strongly in connection with the subject of making stereoscopic slides, which, under suitable circumstances, might very probably prove of exceptional value as a commercial speculation, and that is the photographic representation of family and other groups in *natural* positions. Successfully achieved, such a style of presenting portraits would certainly be appreciated, and, in all probability, supplant the flat-looking, very-much-thrown-together-and-heaped-up mass of inanimate form sometimes designated a family group likeness. Whether such a dire catastrophe would indeed follow a perfect, or approximately perfect, stereo, little matters now, my intention being to direct notice towards a means of interesting the general public in order that the fraternity may derive some definite advantage.

Believing firmly in the prospect of a demand for group photographs such as those indicated, I should like to trespass on your patience a step further and intimate the kind of instrument which I think suited for carrying out the suggestion. The ordinary portrait combination ranging between four and a half and six inches focus will be found as practicable as any. Although it would be inadvisable to use such a lens at full aperture, the employment of a small diaphragm is not only unnecessary but positively objectionable if one desires to secure soft, harmonious, well rounded impressions. Then, again, if complete success is to be attained in this class of work, anything short of a commodious and well lit studio cannot be relied upon. Properties, many and varied, have to be requisitioned, and the means of properly illuminating the same ought to be under perfect control.

With regard to pairs of lenses for securing two images from different points of view at the same time, I must say that I have never met with two instruments absolutely accurate when paired, there is always something wrong about one of them either in focal length or brilliancy of image. This may not be the general experience, however.

With the routine of ordinary manipulation I will not occupy your time, but pass to one other form of slide which can be made exceedingly interesting. That to which I desire to draw attention is the subject of interiors of dwellings, churches, and also exteriors generally, such as street views. Many of these, when illuminated and deeply printed to convey the idea of night, afford much amusement. As most of those present know perfectly well, these effects are produced by colouring the back of the print similar to the method of colouring crystaline. The print is backed up with a suitably coloured ground, and where lights are required, such as candle or gas flames, holes corresponding with the position are punctured with a needle point. Slides of this description are examined by transmitted light like ordinary transparencies.

Sufficient has been brought under notice to raise an opinion on the possibility of progress in the direction indicated, and should these hurried and disjointed sentences fail in their object, to the lack of careful preparation must their failure be ascribed.

Mr. Faulkner did not find in ordinary paired stereoscopic lenses any such difference as affected the identity of the two pictures. It was wonderful how great might be the dissimilarity of the lenses without a difference being discoverable in the unity of the stereoscopic picture.

The Chairman said that there would be no difficulty experienced in getting the work properly executed; the real difficulty lay in getting the public to appreciate and order stereoscopic portraits.

A Member: It should be the province of the photographer to cultivate the public taste and bend it in this direction.

INTENSIFICATION.

By W. B. BELTON.

I HEARD an amateur remark a short time ago, "I never intensify," and I felt inclined to retort, "Perhaps it would be better if you did;" but as I thought he might recognise the truth of the reply, and I did not wish to hurt his feelings, I refrained. It is all very well and very pleasant, no doubt, to be able to dispense with the operation of intensification, but who, that values his reputation for uniformly good work, will undertake to do without it altogether? It is absolutely necessary at times, even under the best of arrangements, and the most careful working, and he who says, "I never intensify," is either a *perfect* manipulator—which I don't believe—or a careless one who takes little true pride in his work, which is more likely.

But intensification has got into sad repute in connection with gelatine plates, owing to the liability of the intensified image to change, fade, or become denser with time and exposure to light. This applies equally to all forms of intensification, though mercury, in some of its forms, has secured the worst reputation; still, I have little hesitation in expressing the opinion that the instability is not due to the method of intensification, but to the want of care in preparing the film to receive it. I have negatives which were intensified seven and eight years ago, by one of the most distrusted of mercurial methods, that are as good to-day as when newly done; I have others, again, or the remains of them, that exhibit every form of defect that can come from mercurial change.

Silver intensification on the other hand, though the practically universal method employed with collodion plates has gained little favour with gelatine-bromide workers, on account of the liability to stains and discolouration of the film during the operation itself; while it has even been alleged that a gelatine film which has once been touched by a solution containing a soluble silver salt is doomed to discolouration sooner or later.

With regard to the liability to stains, I have frequently endeavoured to show that it is far easier to prepare the gelatine film for silver, than for mercurial intensification, but the difference is that a degree of carelessness that suffices in the case of silver to produce immediate change will be more tardy, though no less sure in its effects when mercury is employed. The change produced in the one case is, in fact, instant and complete; in the other, deferred, gradual and incapable of check. With silver, and only moderate care, the change or stain may be but slight; with mercury, under similar circumstances, the utter ruin of the negative is only a matter of time.

As concerning the alleged after deterioration of silver-intensified negatives, I can only say that I have some that were treated in that manner in the summer of 1880, and which, up to the present time, have exhibited not the faintest sign of any sort of change; and I will say further in connection with them, that if there be any virtue in the oft-vaunted "wet plate character," they possess it in far greater degree than others treated in a different manner, or not intensified at all.

Silver intensification is, and always has been, my favourite, where permanency of result is required (if a negative be only required for temporary purposes, it is not worth the trouble), but recently I have modified my method of using it. Previously I have adhered to the formula frequently given in the JOURNAL and ALMANAC, in which solutions of plain pyro, and of silver acidified with citric and nitric acids, are used; but latterly I prefer to employ a solution of pyro, citric acid, and glycerine, with a separate solution of silver acidified only with nitric acid. The advantages of this method are, that the solutions will keep indefinitely, or practically so, and that the glycerine causes the intensifier to flow readily over the film, enabling the operator to use a very small quantity, pouring on and off the plate, and thus economising silver, as well as saving the trouble of freeing the back of the negative from the dense deposit of silver that occurs when a dish is used.

I make the following stock solutions:—

A.	
Pyrogalllic acid	10 grains.
Citric acid	2 "
Glycerine	1 ounce.
Water	1 "

B.	
Nitrate of silver	60 grains.
Nitric acid	30 minims.
Water	1 ounce.

For use dilute one part of A with two parts of water and pour on to the plate, leading it to the edges with the finger or a camel-hair brush, if it refuse to flow alone. One drachm of pyro solution mixed with two drachms of water suffice for a half-plate. When the solution runs smoothly over the whole surface return it to the developing glass, into which half a dozen drops of B have been placed, and again apply the

mixture to the film, keeping it in motion all the time. The density comes rather slowly, and it should be borne in mind that it increases greatly on drying the negative, so that allowance must be made for that.

The only preliminary preparation the negative requires after fixing is a *thorough* washing, but this may be supplemented by a minute or two's soaking in alum and hydrochloric acid as a final precaution. Removal of the hypo by means of eliminators, instead of by washing, is worse than useless; besides which, such substances as the hypochlorites, hydroxyl, or even alum when long applied, destroy the power of intensification. The negative is, therefore, better if simply washed. Should a slight yellow stain appear after prolonged treatment, it is easily removed after the operation is complete by a short re-immersion in the alum and hydrochloric acid, provided it is only *silver* stain and not hypo. The final dip in alum and hydrochloric should always be given in order to destroy any free silver that may remain.

Intensification is more rapid *before* fixing than after; but unfortunately, with gelatine plates, it is most difficult to judge accurately of the density. It may often happen, however, that when a very thin image has to be treated, the application of the intensifier, before fixing, will prove advantageous.

Mr. A. I. Henderson thought that the application of hydrochloric acid and alum would cause a formation of chloride of silver in the film, and they all knew how such chloride would behave under the action of light. A dip into hyposulphite of soda would, he considered, act better. As an intensifier, mercury, followed by cyanide of silver, was believed to be the best. But photographers now preferred to err on the side of over developing, and afterwards reduce the negative, where necessary, by Farmer's method of immersing in a bath of red prussiate of potash and hyposulphite of soda.

Mr. J. M. Turnbull said that there was a form of intensifier recommended by Wratten & Wainwright which bore a great similarity to that just described in Mr. Bolton's paper, with the exception of the addition of glycerine. Intensification had been much resorted to in former times; but now the negatives were usually developed to full intensity at once. Subchloride of mercury, or calomel, when dissolved in iodide of potassium, made a very simple and excellent intensifier.

After some observations by Mr. J. B. B. Wellington,

The Chairman could not speak with approval of the system advocated by Mr. Henderson: in his own hands, at any rate, the action of Mr. Farmer's reducing mixture had a tendency to render the negatives hard by unduly weakening the shadows.

THE PHOTOGRAPHIC USES OF NITRITE OF POTASSIUM.

By H. H. O'FARRELL.

MR. W. A. GREENE recently exhibited at the Camera Club a specimen of a print which he had taken on bromide paper that had been treated with nitrite of potassium. This is the same paper that is issued with the commercial actinometers, and the possibility of using it for printing out has doubtless suggested itself to many, though I have not seen any specimens other than those exhibited by Mr. Greene. I have lately been making some experiments on the use of nitrite of potassium both in the paper and in the developer, and having been called on at very short notice to contribute a paper for the Convention, I think a short description of the results may not be uninteresting to those who are working, or would wish to work, in the same direction, though from the limited time at my disposal, as well as from other causes beyond my control, the experiments are far from complete.

The method I adopted was to make up a ten per cent. solution of nitrite and soak the paper thoroughly, leaving it immersed for ten minutes or a quarter of an hour, and then allow it to dry slowly. The paper thus treated behaved in the ordinary way that the actinometer papers behaved, toning to a greyish blue, which deepened afterwards into indigo. By placing the paper between the leaves of a book and drawing out a portion every five seconds, I found that in strong sunlight the paper attained its maximum density in twenty-five seconds, and that beyond that period no perceptible change occurred.

A portion of the paper, however, which I treated somewhat differently, behaved in a different way. Instead of turning a greyish blue, the paper began with a delicate pink, deepening to a litmus red, and afterwards a brown, before taking on the ordinary blue and indigo tones. Having by me a negative of an individual with brown hair, I conceived the idea of taking a print, with the happy result that by arresting the operation at the stage when the flesh tints had acquired sufficient depth, the hair had toned down to the brown stage, and the coat to indigo.

I conceive some use may perhaps be made of these results not in colour photography but in the more limited area of colour portraiture. A paper which gives flesh tints, browns, and indigo blacks, possesses a sufficient range for the portraying of persons other than the ancient Britons who stained their bodies with woad, or the late Mr. Tittlebat Titmouse, whose hair at one period of his existence assumed a pea-green colour.

At present, however, there is a difficulty to be overcome which is the same that has hitherto proved a stumbling block to all colour photography—the difficulty of fixing the prints by means that will leave intact, and at the same time render stable, the tints obtained. Hyposulphite of soda destroys the colours at once, bringing back the blues to the original pink, and ultimately changing them to a very unpleasant yellowish brown.

Hypo being therefore out of the question, I next thought of sulphite of soda, which has been recommended by Captain Abney as a fixing agent for albumenised prints. To my great satisfaction, I found that the sulphite had no effect upon the colours, and after leaving the prints for about half an hour I concluded they were fixed. So, indeed, they were in the sense that the free bromide had been removed and the image rendered permanent, but the pinks and browns still remained fugitive and ultimately deepened in strong light to a blue tint.

I have not yet tried other fixing agents, but hope to do so shortly. At present, however, I see no prospect of being able to render the pink or brown tints permanent.

Nitrite of potassium used in small quantities in the developer (about twenty to fifty minims to the ounces of a ten per cent. solution) appears to have a considerable accelerating influence. I exhibit specimens of prints which have had the same exposure and were developed with the same developer with and without the addition of nitrite of potassium.

I have also tried the effect of soaking plates in the nitrite solution and exposing in the camera. I obtained on a dull day a faint image of the high lights in five minutes and a badly defined picture with thirty-five minutes' exposure. The image was, however, capable of intensification or development by a *very* weak solution of ferrous oxalate—about one part of iron to twelve of oxalate. The result, however, faded considerably in the fixing bath—hyposulphite—but appeared to be capable after fixing of intensification with the ordinary ferrous oxalate developer.

I am afraid this paper is necessarily imperfect and sketchy, but I shall be glad if it leads more experienced experimenters than myself to investigate the phenomena. Two cautions are necessary in using this very hygroscopic salt with plates—to immerse the plate in alum *before* developing in order to avoid frilling, and to use the nitrite solution fresh.

EXPERIMENTING.

By H. J. GIFFORD.

IN looking over the papers of the present day, what strikes me is the vast number of photographers we have experimenting, and how few of them know really how to experiment. They give some of their results, but not all; and even those results are not of any use, owing to some point having been forgotten.

I think it might be useful to some if I pointed out some things which ought to be noted. First, the note-book with the notes of the experiments ought to be kept in such a way that if it was handed to any one else he could perform the experiments over again, and get the same results.

The chemicals used ought to be of the purest obtainable; the maker's name and date of obtaining noted, and if possible tested for impurities, as the results obtained may be due to reactions of the impurities instead of the salt. The distilled water also ought to be carefully tested for iron, &c., which it often contains, the first and last portion passing the still being discarded.

Thermometers ought to be in use constantly, and where gases come into consideration the reading of the barometer also. In boiling solutions the process ought to be described in this way:—Temp. 62°, in twelve minutes, 212°; boiled half an hour, bulk reduced 120 c.c.; cooled to 62° in one and a half hours; barometer at beginning of operation, 30·213; at end, 30·209.

PHOTOGRAPHY FROM ONE POINT OF VIEW.

By EDWARD DUNMORE.

It is usually the case when allusion is made to photography to speak of it in its dual name as an art-science. Now, for the purposes of this paper, we will ignore the science definition, retaining only the art, thus looking on the scientific side of the matter very much in the same way as a painter or engraver looks on his colours and appliances. I am somewhat doubtful if, by thus invariably linking together of art and science in name, we have not produced a bad effect on photography as an art. Whether or no it has had considerable influence in keeping its artistic qualities suppressed I am not prepared to say. At any rate, photographs are, and always have been, looked upon by many as merely mechanical productions, incapable of expressing a thought, suitable only for producing literally just the matter-of-fact subjects that may be presented to the lens. This is, in my opinion, undoubtedly an erroneous idea. That the photographer has, if he be clever in his profession, the power of imbuing his work with his own individuality in a very marked manner, there is not the slightest doubt. Who could fail to see the man in the works of Rejlander, Robinson, Hubbard, Diston, and others? This fact is alone sufficient to prove that a camera and lens, skilfully used, is something more than a mere mechanical copying machine. We see by actual work that picture making by photography is not only possible, but has been actually accomplished. I speak here in the past tense, by reason of having in my mind the pho-

tographs that impressed me most as *pictures*, and which, I have no doubt, many here will associate with the names of the artists I have enumerated. Photography is not easy, by any means, to work as a *picture* making process. The ease with which an image is obtained is illusory, pictures and images not being synonymous or interchangeable terms. It reminds one of learning the German language, which at first sight has many of the words looking so very English that we jump to the conclusion its acquirement is very easy, and not until we have dipped into it we find out our mistake, and that the apparent ease is but delusive. The gay and airy manner with which we thought of mastering it is soon dissipated, instead of which we are involved in a struggle with words that is a formidable and unexpected task to the greater portion of those who make the attempt. It is so very much more easy to blame the process when we fail in our attempt at picture making than to use it. It is no reason because there are undoubted difficulties in the way that we should fall back on that very poor excuse for not making good pictures. Certainly not. It has been satisfactorily proved that pictures in every sense of the term can be made by it, and by patience and perseverance the difficulties must be overcome; the more of them the greater the victory. The well-worn aphorism that "the bad workman blames his tools" is especially applicable to photographers and photography. We know the tools are generally good, and it is our own fault if we do not make good use of them. I sometimes think they may be too good; and when we see such a display of French polish and ornamental brass work, and the very, very small results, it makes one think perhaps if there were less thought for the apparatus and more for the picture it would not be a bad thing.

It is very difficult to satisfactorily define "art," so general is the application of the word in season and out of season. If a tradesman gets particularly ugly patterns in goods they are dubbed "art" productions. The elasticity of the term meets all requirements, from a picture to a funeral. So much, then, for the application of the term "art," upon which I will not further enlarge. Then we get "fine art," even a more debatable term than the other, but not quite so universal in its application. It is, however, decidedly more provocative of wordy conflicts. As to the precise meaning of the term opinions differ; our purpose will be served if we define it as anything beautiful of a more decorative than useful nature, under which head a good artistic photograph may be fairly classed. A photographic picture, then, is an application of the process of photography to represent nature in conformance with the rules that masters in the art of painting and draughtsmanship have laid down as applicable to their particular branches, especially in composition and chiar-oscuro. For the present, at any rate, laws relating to the treatment of colour do not particularly concern us, except when colour takes the place of light and shade, and has to be considered in that connection.

Artistic photographic pictures may be classed under three heads: land or seascapes, *genre*, and still life. Photographs may all be fairly included under one or other of these headings. The landscape into which figures are introduced, if the figures should be so composed as to tell some tale by which the interest will be fairly divided between figure and landscape, have given rise to a variety of opinion as under which head such pictures should be classed. A compromise has been made by denominating them as "landscape with figures," a style which Birket Foster's water-colours have so admirably exemplified. In these productions we have action and interest in the arrangement of the figures, yet without destroying that of the landscape, which, by its freshness and suitability, claims almost equal attention. In the composition of pictures of this kind, to which undoubtedly photography lends itself, the *proportionate* size of the figure to the landscape entirely decides the class to which it shall belong if figures are introduced in the foregrounds and treated in an important manner. We should scarcely call that picture a landscape, but if placed in or beyond the middle distance they become subsidiary to the landscape, and the picture may be fairly called a landscape with figures, or the figures may be dropped in the title altogether. There are few, if any, landscapes the interest in which is not increased by the addition of figures. Particular attention should, therefore, be given to their position and arrangement, for awkwardly posed figures in the wrong place will ruin any landscape, however beautiful. The foreground in all landscapes should receive very careful attention, for upon this part of the picture much of the general effect of the work depends, it being close to the eye and upon a larger scale than the rest at once challenges attention. Its arrangement and detail should therefore be most carefully looked to. Many hold, I cannot help thinking, very erroneous ideas as to what constitutes a picture, a "good photograph" being considered synonymous with a "good picture," when, to my idea, they are as far apart as the two poles. However, this is not a suitable opportunity to enter into a long argument as to what constitutes a picture, suffice it to give a few examples of what do not; e.g., a photograph of beautiful clouds, although pleasant to look upon, scarcely constitutes a picture in itself, but add the merest strip of landscape that has pictorial interest and it at once becomes one. A picture must be a combination of several things, each of interest in itself, otherwise it remains a mere photograph; it may be an excellent representation of the object, but without any claims to pictorial honour. This is a rock on which many get stranded, having the idea that a good photograph of any particular object, no matter what it is, is of necessity a good picture. The sooner this idea is exploded the better for everybody.

The more skilful the composition and the better the judgment shown

in lighting, the more a work of art a photograph becomes. In these two directions photographers should especially try to improve themselves. Their appliances may be more difficult to work with than those of the painter to obtain results of an equivalent pictorial value, but difficulty should scarcely be an excuse for indifferent work. I would therefore urge the study of art in its various phases by all who have a desire to produce more than mere photographs; it will not be time thrown away. Can any one suppose any accomplished painter made grand pictures as soon as he knew how to manipulate his colours? and yet many photographers expect to do so directly they have acquired sufficient skill to make a negative. The idea is absurd; years of study and practice and many disappointments must necessarily be experienced before a clever and finished work can be exhibited for public criticism. Why, then, should the photographer be an exception to the rule, and why should one who has really greater difficulties to contend with imagine he can make a *picture* (except by accidents, which in all probability can never be repeated) than a man who by laborious study has learnt, after many failures, to properly handle brushes and colour? The conceit engendered by the ability to make a mere representation of a subject without the most rudimentary knowledge of draughtsmanship encourages the performer to entertain a false estimate of his own skill, a result undoubtedly prejudicial to real progress. True artists will always be in the minority; it is only here and there a man or woman without, perhaps, any decided manipulatory skill will come to the front by reason of their artistic ability. A more slovenly manipulator or more artistic photographer never lived than O. G. Rejlander. No matter how messy and defective his work from a chemical point of view, the *picture* was there; and, had he lived to enjoy the advantages of photographers of the present day, in all probability good manipulation would have been added to his superlative artistic treatment of subjects to which he turned his attention. With the wet plate of his day a man essentially an artist was woefully cramped and handicapped, for to make a complete success you were compelled to think of the plate. When the whole attention should be centred on the *subject*, this division of interest was a great drawback. Nobody knew it better than Rejlander. Now, however, we can devote our whole attention to the subject, and in the click of a shutter secure any beautiful effect, if we only know how to look for it and to see it when it presents itself. We must see a picture before we can photograph it; if we do not, it is pure accident, and can never in human probability be repeated. This is a reason why a man's skill should not be estimated on the strength of his producing one superlatively good work, for the veriest duffer is sometimes lucky in this respect, and such having received an overwhelming avalanche of commendation is a spoilt photographer for the rest of his days. The ability to see pictures varies with everybody, and to this we owe the great variety of treatment the same subject will receive at the hands of different photographers. Some are artists intuitively, some by education, and some not artists at all, either intuitively or by education, and never will be. Yet all expect to make pictures. We know they cannot, but it is little use saying so. The few go on and succeed, but the ruck never get beyond mediocrity. As soon as any one is satisfied with his work it is all up with progress; his ideal standard of perfection is a very low one, soon reached and never exceeded.

In these days of education and opportunity photographers should be amongst the first to take advantage of our art schools, and not rest in smug contentment, fancying they are independent of anything of the kind because the schools are specially devised for instruction in drawing and painting. The means used may differ, but the aim is picture making, and rules which govern one process will rightly influence another. The knowledge of art is one of the things to which there is no royal road, and it is only by practice, perseverance, and painstaking, that we can hope to see photography raised to that position that it will be no misnomer to call a fine art. Absolute perfection in things mundane is not to be expected, but our endeavour should be to get as near to it as possible. As a proof of how long photographers will be content to run in a groove until started out of it, we have only to go back to the time of Adam Salomon; his exhibits were so excellent and so different from anything English photographers had conceived possible. Like a revelation, it could be scarcely credited that by the aid of the well known silver bath and collodion such rich masses of light and shadow could be produced, but they did. Then there was the pose and composition of the pictures; nobody had conceived portraits arranged with such simple grace and so brilliantly lighted without hardness could be made by photography—but they were. The only difference was the process was directed by a master's hand, that was all. From the time his pictures were exhibited English photographers began to see the tools they worked with were capable of much more than they had suspected, and a vast improvement in portraiture and artistic management of the picture immediately took place.

With landscape work there is no such thorough revolution likely to take place, for as good pictures were taken years ago as now of the subjects to which photographers were then restricted. The most charming effects of light and shade were reluctantly passed; the prompt exposure at the right moment was well nigh impossible, for by the time the wet plate was ready the effect was gone. Photographers were in consequence limited to evenly lighted views. The uniformity accruing from this cause

gave rise to the depreciating term "photographic" when applied to other pictures. Now, however, the rapid dry plates have placed the long wanted power of being ready at a moment's notice in the photographer's hands, and any effect, no matter how transient, may be secured. The abuse of such power by exposing on anything that comes must be avoided, and there is no doubt that when the novelty wears off it will be. We now have a grand chance of making real pictures, such that we scarcely did more than dream of formerly; we have, therefore, a right to expect a corresponding improvement in our work.

Mr. J. J. Briginshaw then read the following statement, which he had received on behalf of the Photographers' Benevolent Association, copies of which were distributed among the members of the Convention:—

"We, the undersigned, have been deputed by the Committee of the Photographers' Benevolent Association to bring under the notice of the Photographic Convention of the United Kingdom, at their meeting at Glasgow, a statement setting forth certain claims the Institution has upon the fraternity.

"The Benevolent Fund was inaugurated in 1873 with the sole object of helping indigent and infirm members of the craft who were found to be deserving of substantial sympathy, such cases as those arising from sickness, death, or prolonged lack of employment, being considered to be eligible. From the commencement of the Society's labours up to the present *bona-fide* applicants whose contributions entitled them to benefit have been as liberally dealt with as the funds at the disposal of the Committee for the time being justified, or was deemed adequate. The Society has thereby greatly lightened the tax imposed on individuals who might otherwise have been called upon to dispense private benevolence under circumstances sometimes the reverse of agreeable.

"Much remains to be done in order to carry out the intentions of the promoters, especially in the direction of the education of orphans and giving annual pensions to the aged. For these special objects, as well as assisting in the general scheme, the Committee appeal, through the members of the Convention, to all interested in photography, whether actively engaged therein or not, to aid them in their endeavour to build up an institution worthy of the present status of our profession. The first step towards attaining this much-desired end is to strengthen the hands of those already engaged in the work by each and all entering heartily into the spirit of doing good unto others. An annual subscription of 2s. 6d. constitutes membership, and this sum is so insignificant that no one could with any semblance of truth be found to say that such contribution was beyond his means. In case there be any misconception, it may be at once stated that the funds have not accumulated to their present state with such small payments, but from the generous donations cheerfully given by amateurs and the more wealthy members of the profession.

"Donors of one guinea per annum are entitled to the privilege of recommending deserving cases of non-members for the consideration of the Committee in addition to possessing equal rights in controlling the management of the Society with ordinary members. The Association is registered under the 'Friendly Societies' Acts, and it may further be stated that a thoroughly representative Committee of twelve members of the Association, jointly with the following gentlemen, guide the fortunes of the Institution.

"President: J. Traill Taylor.—Trustees: Capt. W. de W. Abney and Walter S. Bird.—Treasurer: John Stuart, 112, New Bond-street, W.—Central Secretary: H. Harland, 83, Hawksley-road, Stoke Newington, N.—Committee Rooms: 181, Aldersgate-street, London, E.C.—
"Signed on behalf of the Committee—W. M. ASHMAN. EDOAR CLIFTON."

Mr. Taylor, by whom the papers of the absent members had been read, announced that at the Wednesday evening meeting the chair would be taken by Professor A. S. Herschel, and that after the reading of several papers, a second lantern entertainment would be given, during which would be shown a choice collection of selenite and other slides by polarised light, Mr. Briginshaw officiating as demonstrator.

On Wednesday morning a numerous party went on an excursion to Loch Lomond and Loch Long, under charge of Mr. John Stuart, and an equally numerous contingent went by special steamer, under charge of Mr. George Mason, to witness the yacht regatta at Largs.

The Exhibition Department of the Convention is singularly fine; but we must defer all notice of it till next week.

CONVENTION JOTTINGS.—I.

(By our Special Correspondent.)

We started from London by the Midland for Glasgow on Friday night, July 1. The Convention meetings beginning on Monday morning following, we wanted to have a look round on the Saturday

and make a note of the preparations previous to the bustle which we expected in the beginning of the week.

An item in a select party, we got comfortably laid out in a compartment, and arranged ourselves so as to obtain the greatest amount of comfort out of limited space, and we packed pretty well. It was too hot for anything but lounging; even when a good joke was perpetrated it was an effort to laugh, and we really had to think a laugh, if you could conceive such a thing. We all, as usual, did a sleep now and then, and each starting up in turn would assert that he had not slept at all, and for a minute or two would look round—so very wide awake—then the eyelids would gently drop and the nose would make an audible indication that the protestor was away again. At a very early hour in the morning B— exclaimed, "Oh, look at the beautiful fireworks!" (he had been evidently dreaming about the Jubilee), but he was mistaken, it was nothing so short-lived or expensive—'twas but the rising of the sun, and he sat and gazed at it, highly delighted. "The beautiful in nature goes on all the time," he said, evidently thinking of writing a poem. "The slumbering world moves along unconsciously, and the glorious pictures in the heavens unroll themselves one by one, passing by unheeded, uncared for."

"Yes, B—, and if you hadn't been on the night shift, you would have been one of the slumbering world too," said P—, as he rolled himself over on his seat. He was not in a mood for sightseeing.

I remembered once on this journey when crossing at Settle having a beautiful panorama of hill and dale, so charming that it has lived with me ever since, and eagerly I waited for this. But nature was not in the mood, or I was too sleepy; the outline of the hills were veiled, or my eyes would not keep open. There was something wrong somewhere, and I gave it up, drooping off into unconsciousness.

As we reached the commercial capital of Scotland, we found a gentle rain falling that was very refreshing—a mist, I think, it is termed in these northern latitudes. As they have been baked hard with the continued intense heat here as much as we have been in the south, this moisture was welcomed all round. We arrived at the "Waverley Hotel," and freshening ourselves up outwardly and inwardly, we prepared for a day's enjoyment. We began the day's proceedings by visiting the Institute of the Fine Arts, where the meetings, and exhibitions, and lecture entertainments are to be held, and Glasgow deserves great credit for the very handsome way that everything for the convenience and comfort of intending visitors to the city has been arranged and fitted up. In fact, it is in its method of arrangement a "British Association" on a small scale.

In the one building there are ladies' and gentlemen's rooms, writing rooms, smoking room, secretary's room, exhibition and entertainment rooms, and all done up with great taste, combined with attention to the perfect comfort of the visitors.

The exhibition of pictures alone would be worth coming a long way to see, and Mr. Robert Turnbull, who is the chairman of the exhibition committee, deserves both thanks and praise from the Convention for the very able manner that he has performed his part of a very arduous task, for when we visited the rooms on Saturday everything was done, and well done; and when it is said that all this work under his management was begun and completed within two days, the visitor has but to look round and see the "something attempted, something done" to earn the meed of praise.

After inspecting the rooms, and shaking hands with a few old friends, we started out to see the city from the top of a car (this is the proper way to see a city), under the conductorship of Mr. George Mason, who took us over about fifteen or twenty miles of streets—north, south, east, and west. We viewed the palaces of the merchant princes, and looked into the hovels of the lap-eed masses. We inspected the beautiful parks, and the Greens where the toilers have a chance of breathing the fresh air in their leisure moments. And last, though not least, we came upon that venerable edifice, Glasgow Cathedral, where the story of the genius of our forefathers is told in silent stone, on which we but look to read that there were giants in the land in those early days. The stained-glass windows in this edifice are supposed, for number and beauty, to be almost unrivalled in any one building. These windows are modern, and in many cases are the gifts of wealthy donors. Behind the Cathedral is the Necropolis, charmingly situated on a hill which rises ridge on ridge. As we stood looking at it, "We must have a picture of that!" was the

exclamation of all. We got home to our hotel, and after a good dinner got into the smoke room, and where a few of us are met together we indulged in matters photographic, of which more anon.

Sunday was a very quiet day in Glasgow, and there were no chances of getting outside of the city, both the steamboat and railway traffic being entirely suspended. Several members somehow contrived to arrive in the morning, and when "Joe," of the "Waverley," announced that dinner was on the table, no fewer than thirty-two ladies and gentlemen were found ranged around the well-spread board, presided over by the Chairman of the Convention's Council, and supported right and left by the Secretary and other brethren.

Of the genial gossip which took place over the fraternisation in the smoking room nothing need here be said, as it is easy enough to conceive of it.

On Monday the yacht-shooting mania seemed to be strong on some of us, and a party headed by Hyslop and Pringle went down the Clyde, bent on capturing the graceful "white-wings;" while Keene (father and son), Jerome Harrison, and a party whose predilections were archaeological, paid their devoirs to the Cathedral, leaving Wellington, Smith, and a considerable party—who, having come north *via* steamer, had arrived in the best of spirits that morning—to ply detective cameras in the busy thoroughfares and along the Broomielaw.

CONTINENTAL PHOTOGRAPHY.

[Translations and Abridgments.]

THE FLORENCE PHOTOGRAPHIC EXHIBITION.

At the present Photographic Exhibition in Florence, the jurors, who have all been elected by the exhibitors, are Professor Luigi Borlinetto, Giuseppe Alinari, Anselmo Anglinelli, M. Nadar, Professor Cesaré Zocchi, the Chevalier Emilio Trèves, the Chevalier Ulisse Granchi, the Marquis G. Gozzoni, the Chevalier F. Alman, Count Lodovico de Courten, Professor M. Gordigiani, Captain Pizzighelli, Professor Léon Vidal, Carlo Brogi, A. Corsi (engineer), Professor P. Stefanelli, Giovanni Berti, and Professor F. Andreotti. The first meeting of the jurors was on the 10th of this month, and M. Léon Vidal left Paris to be present thereat to perform his duties, and to gather materials for publishing in France a full description of the Exhibition.—*Le Moniteur de la Photographie*.

PINHOLE CAMERAS.

At present efforts are being made in France to develop pinhole cameras so as to yield the highest results they will give. Messrs. Dehors & Deslandres have invented a camera furnished with a variety of pinholes of accurately measured dimensions, and constructed for taking both ordinary and stereoscopic views. By means of a rotating disc, any particular pinhole can be brought into play. With pinhole cameras the widest possible angle is included, the images are entirely free from distortion, and are always in focus, whatever the distance of the ground-glass from the pinhole.—*Journal de l'Industrie Photographique*.

PHOTOGRAPHY IN PICARDY.

A few months ago but a single photographic journal in France, that of Versailles, was printed by lithography; a second has entered the field, namely, the *Bulletin* of the Photographic Society of the North of France, published at Douai. It bears the signatures of the President, Monsieur G. Maugir, and of the Secretary, the Abbé Vandy.

At a meeting of this Society, held on the 18th March, Lieutenant Sirvin exhibited a panoramic camera of his invention for taking photographs upon paper. At its meeting on the 22nd April, M. Groult exhibited a stereoscopic camera with a magazine of plates, which could be brought into position as required for exposure. He also exhibited specimens of good work done with the instrument.

This Society has written a very important letter to the President of the *Commission d'Organisation* for the *arrondissement* of Douai requesting the organization of an International Congress of Photographers on the occasion of the International Exhibition in Paris in 1889.

The lithographed journal of the Photographic Society of the North of France contains also an illustration executed by photographic means. Its second number contains a representation of the ancient gateway of the Chateau of Ferté-Milon, reproduced by M. Berthand, of Paris, by phototypy. The negative was taken by M. Edmond Bayard.

The writing in this lithographed journal is too small; it is trying to the eyes of readers, but very well executed.

THE "BULLETIN BELGE."

The *Bulletin de l'Association Belge de Photographie*, published at 37, Rue Souveraine, Brussels, has always been a journal of first-rate quality, but this year additional improvements have been introduced, until as a monthly photographic journal it is without a rival. Its May number contains a frontispiece by the Woodburytype process, executed by Brann & Co., of Dornach. It consists of a copy of the picture which carried off the gold medal at the Belgian Photographic Exhibition, representing the interior of a blacksmith's shop; the original photograph was the work of M. Georges Wilmotte. The official report of the General Secretary says that the reputation of the *Bulletin* is increasing in foreign countries, and that its circulation abroad is increasing likewise.

ORTHOCHROMATIC PHOTOGRAPHY IN BELGIUM.

At a recent meeting of the Brussels Section of the Belgian Photographic Association, M. Gêruset gave the results of his experiments with orthochromatic plates, and said that the best had been obtained by him upon those made by Mr. Edwards, of London; the plates were also quite as rapid as the ordinary ones he had in daily use. He thought orthochromatic plates to be a great advance in photography, that they gave more truthful results than other plates, and diminished the work of the retoucher. M. de Blochouse was of the same opinion. M. Rutot raised the question whether a deep blue would not be the best light in which to develop orthochromatic plates, since that colour seemed to have little effect upon them. The President, Signor O. Campo, called attention to a brown kind of paper, now coming into use in Germany, said to permit the passage of a good light for developing, and one not fatiguing to the eye.

THE DEATH OF AUGUSTE FLORENVILLE.

The report of the Secretary-General of the Association Belge announces the death of Auguste Florenville, who assisted at the birth of photography, and who passed away recently at Liège after a short illness. Florenville, after reading about the discoveries of Daguerre in the annals of the Academy of Sciences at Paris, immediately went in search of the inventor, and they tried various experiments together, the results of which were recently publicly exhibited. With apparatus furnished by Daguerre, Florenville returned to Liège, and carried on experiments in photography with the Baron de Wittert. One of their first satisfactory results was a portrait now in the possession of M. Laoreux, with the following words upon it:—"September 1839—*Pose seven minutes at two o'clock in the afternoon.*" Florenville never ceased to study photography in his leisure hours, and among those who learnt under him was the present President-in-Chief of the Belgian Photographic Association, Dr. Candèze. For a great many years Florenville was a member of the Council of the Association.

The same report has a notice of the death of Léonce Rommelaere, the founder of the Belgian Photographic Association, and the Director of the Industrial School at Brussels, whose lamented decease has already been published in these pages.

MISCELLANEOUS ITEMS.

An "Excursion Society of Photographic Amateurs" has been started in Paris, under the presidency of M. Gaston Tissandier, director of *La Nature*.

It is proposed to found a new society, under the name of "The Parisian Photographic Association," and the proposal seems to be creating a little friction.

The London correspondent of *Le Moniteur* says that when he read in the *Times* that Mr. Mayall had discovered a method of producing photographs in natural colours, it gave him a little electric shock.

The *Journal de l'Industrie Photographique*, says that in America some journals have furnished their reporters with detective cameras, with which they take instantaneous views of events of interest, and send off transparent proofs to the editors. Each proof is then placed in a lantern, the image is projected upon a paper screen, upon which a draughtsman at once begins to work with ink and brush. The result is reduced by photography, engraved or otherwise, made into a printing block, and then is worked off upon the machine with the text of the journal.

" 14	Bradford Amateur	Grammar School.
" 14	London and Provincial	Mason's Hall, Basinghall-street.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, June 30, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. A. Mackie presided.

The Annual General Meeting of the Association was adjourned for a month. Mr. W. M. ASHMAN suggested that the occasional markings round the edges of gelatine plates might be discussed.

Mr. J. J. BRIGINSHAW said that they were usually ascribed to the action of sulphurous matters in the atmosphere.

Mr. W. E. DEBENHAM believed that to be the true explanation, and that the only remedy was to enclose the plates in hermetically sealed packages.

The CHAIRMAN stated that the markings could sometimes be abolished altogether by soaking the plate in the ammonia and bromide before applying the pyrogallol.

Mr. DEBENHAM added that they could often be removed altogether after the final washing of the negative by then rubbing them with the finger under running water.

The HON. SECRETARY asked how it is possible to tell when paper negatives are fixed.

Mr. R. L. KIDD responded that the unfixed portions are more opaque than the others.

The HON. SECRETARY said that the strength of his fixing bath was four ounces of hypo to the pint of water.

Mr. KIDD replied that that was not strong enough for plates; it would do for albumenised prints.

Mr. A. COWAN had never found a half-saturated solution too strong for plates.

Mr. KIDD remarked that when a plate is previously full of moisture it will often be long in fixing, and it may then be advisable to give an intermediate treatment with alum to contract the film; it will then fix readily.

Mr. DEBENHAM had found that there was an enormous difference in the time of fixing of different brands of commercial plates.

Mr. KIDD stated that the fixing solution should be six or eight ounces of hypo to the pint of water. As a rule, the more sensitive the plate, the longer it is in fixing. The best way to render paper negatives transparent was to smear vaseline over them, and then leave them in a warm place for twelve hours. The best way to store them was to put a batch of them between two plates of glass. The vaseline does not penetrate the gelatine film on the face of the paper, so does not come off upon the print.

Mr. ASHMAN asked whether any one knew anything about the Wale lens, which Mr. H. P. Robinson described in the *Photographic Times* of New York as about the best.

Mr. W. H. PRESTWICH thought that it was made in Paris and sold in America.

Mr. DEBENHAM wondered whether it were like some of the Steinheil lenses made in Paris, and sold in England by some of the smaller professed makers.

Mr. KIDD spoke of the advantage of using lenses of long focus for instantaneous views of yachts under sail.

Mr. F. W. COX asked how it was that when a plate was forced in development there was a tendency to develop markings of the paper in which the plate had been packed.

Mr. T. BOLAS said that if an ordinary exposure were given upon a subject with no specially strong high lights in it, and the same plate were afterwards exposed upon another view and with ten times the ordinary exposure, probably not a trace of the first picture would appear on development.

Mr. ASHMAN said that the public are now frequently postponing having their likenesses taken, and are waiting the advent of photographs in natural colours in consequence of what they have read in the daily newspapers.

Some general conversation then took place about the morality of statements made in some of the advertisements in photographic newspapers, in which various persons stated their goods for sale to be superior to all other goods of the same kind.

The meeting then broke up.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The monthly meeting of this Association was held on Thursday, the 30th ultimo, at the Royal Institution. The President, Mr. George H. Rutter, in the chair.

The minutes of the preceding meeting were read and confirmed.

Mr. Vero Driffield was unanimously elected a member of the Association.

The SECRETARY distributed the circulars of the Exhibition of the Royal Photographic Society of Ireland; he also read a letter from the Secretary of the Royal Meteorological Society, asking for photographs of lightning flashes, and calling the attention of amateur photographers generally to the subject.

Mr. R. CROWE remarked that he believed he had taken the first negative in existence of a lightning flash, and would be pleased to let the Meteorological Society see it. He recommended, from his experience, not a rapid rectilinear with full aperture, as advised by the Secretary of the Meteorological Society, but a single lens with aperture not exceeding f_{16} , on the ground that the lightning flash is quite actinic enough to impress itself with the smaller aperture, whereas with the large aperture the plate would be generally fogged by the amount of diffused light present whilst waiting for flashes to occur.

Mr. RUTTER exhibited, on behalf of Messrs. Lange and Mayne, some fine prints in platinotype, also three prints, for comparison, of same negative, one platinotype and two Obernetter's paper, one of which had been squeegeed on glass, the other on ground-glass, so as to compare the effects of enamelled and matt surface. Mr. Rutter also exhibited and explained a Goetz half-plate camera and Morgan & Kidd's roller slide with Rogers's indicator and attachment for employing Eastman rolls. These were examined with considerable interest.

Mr. Kenyon exhibited a number of very fine 12×10 enlargements on Eastman gelatin-bromide paper from quarter-plates and Eastman stripping films, some of which were taken on the Rossett excursion.

Mr. W. A. WATTS read a paper entitled *Notes of a Visit to the Autotype Works*.

Some discussion arose about the difficulty of estimating exposure in carbon printing, some members thinking the reader of the paper had not attached sufficient importance to the difficulty.

Mr. W. H. KIRKBY remarked that with a little practice the difficulty disappeared altogether.

Mr. RUTTER read report of the Bewdley excursion, for which so few gave in their names that it was changed at the last moment to Shrewsbury and Church Stretton. Eight members went, but the weather was unfavourable.

Mr. KENYON read report of the Rossett excursion, from which it appeared that eight members took part and that seventy plates were exposed.

Mr. Kenyon and Mr. B. J. Sayce exhibited some results.

Mr. A. W. BEER reported on the Bolton Old Halls excursion, visiting Turton Tower, the Hall in the Woods, and Smithells. Five members were present, the day being lovely, and from fifty to sixty negatives were obtained.

Mr. RUTTER reported that the Broxton and Carden Halls excursion took place on June 25 in charming weather, five members and two friends taking part in the excursion. The party were met in a most hearty manner at Carden Hall by Mr. and Mrs. Leche. Carden Hall is a very fine old magpie hall with a large amount of carving on the front. Upon inquiry, it was found at the end of the day that fifty-nine exposures had been made, both plates and paper being used, the former being Ilford, Ronch's, Thomas's, Edwards's, and Derwent, whilst the paper was Eastman's ordinary and stripping films.

It was announced that, owing to circumstances, the excursion arranged for July 16 to Irby and Thurstaston had been given up, and there would be substituted for it one to Speke Hall, leaving Lime-street at fifty minutes past one, those wishing to take part to communicate with Mr. C. P. Houghton, 18, Seel-street.

The adjourned discussion on *Paper versus Glass* was then opened by Mr. B. J. SAYCE, who claimed for paper films the advantage on several grounds. He said he had worked on glass many years, but had recently adopted paper, and was quite satisfied with the results, in proof of which he showed a number of prints from negatives both on glass and paper, in many cases of the same subject, and in no case was there any inferiority on the side of paper, whilst in some it was distinctly superior. He claimed for paper the advantage—1st, In weight. 2nd, Facility for changing and therefore for securing a considerable number of negatives in an excursion—the only difficulty was the number of routine operations to be performed, but that could be overcome by systematic arrangement—he employed himself a notebook containing space for initials when wound off. 3rd, Development—he found great latitude, more so than glass; there was some liability to spots, which were quite avoided by the use of plenty of water before development. 4th, Rapidity greater than glass. 5th, Freedom from halation, in illustration of which he showed two prints, one from paper and the other from glass, of the interior of Gresford Church, in which the paper negative was quite free from halation.

Mr. CROWE, on the side of glass, stated that he admitted for paper the one great merit of portability, but with regard to freedom from halation he did not think the film or nature of the material had anything to do with it; the cause of halation was over exposure, in support of which view he showed several negatives on glass of subjects likely to produce halation, but which were quite free from that fault, one in particular of a glass roof with iron supports. He also maintained that the same amount of minute detail could not be obtained on paper as on glass, and showed several negatives containing a large amount of minute detail, which he did not believe could be matched on paper.

Mr. KENYON attributed the freedom from halation shown by paper to the rapidity of development by which it was characterised.

Mr. LEWIS complained of the want of flatness in the Eastman carriers.

Mr. KIRKBY was in favour of paper; he found it more rapid than glass. He advanced the theory that the reason paper is quicker than glass is because in the latter the particles of the emulsion are in a state of strain, whereas in paper it is not so.

Prints and work were exhibited by Dr. Kenyon and Messrs. Sayce, Tomkinson, Ryley, Crowe, Lange, and Mayne, and, after an interesting discussion, the meeting closed at a late hour.

SOCIETY OF AMATEUR PHOTOGRAPHERS OF NEW YORK.

PRESIDENT DEXTER H. WALKER in the chair.

The following questions were asked by Mr. ROOSEVELT:—1st. Is not the time of exposure by far the greatest difficulty in the mechanical part of photography, and can any assistance be given the amateur in determining what it ought to be? 2nd. How do under exposure and over exposure respectively show themselves in the process of development and in the negative when developed? 3rd. After developing a plate with a potash developer as far as it will go can it not be then further developed with a fresh soda or ammonia developer, or *vice versa*?

Mr. SPAULDING, to whom these queries had been submitted, read as follows:—1st. Correct timing of exposures is certainly a difficult matter. In view of the many variable elements that enter into the calculation there is in the nature of the case no help for the photographer except in experience and close observation. The difficulty is, however, less in proportion to the amateur's skill in developing. 2nd. If the developer be freshly made, and of the same temperature, the very short time elapsing before the appearance of the image indicates over exposure. This test, however, I have never found to be of any practical value. We may better judge by the colour, that is, degrees of intensity of the high lights when they first appear. If the high lights have only a very pale black before the rest of the image appears, the plate is over exposed, and needs immediately bromide and more pyro. In other words, we can judge by the rate of development, provided the developer be uniformly fresh and the temperature the same. 3rd. As seen in the reaction, $C_6H_6O_3 + H_2O = C_6H_6O_4 + H_2$ and $2AgBr_2 + H_2 = 2HBr_2 + Ag_2$, the oxidation of the pyro is attended by a constant production of hydrobromic acid, and any acid retards the further oxidation of the pyro, and should therefore be neutralised by some alkali. One alkali will neutralise the acid as well as another. After potash, for instance, has done its work, it would be useless to add soda or ammonia, since there is no more acid for them to neutralise. The above reactions are written separately, but are in reality simultaneous. The pyro will cease to take up oxygen and liberate hydrogen when the hydrogen can get no more bromine; that is, when all the bromine that has been loosened, so to speak, by the sunlight has been exhausted. If more alkali be then added it will only soften the film and fog the plate. I should add that in the development of our dry plates hydriodic as well as hydrobromic acid is produced. All this is, of course, *a priori*. I have not experimented in that direction.

The CHAIRMAN said: This meeting is called to deal more especially with general discussion relating to plates and their development, and of course we want to hear from everybody in the room all they have to say on the subject. In order to start the discussion, I will read a paper, which may be of some interest to you, which was written by Lieutenant C. L. Bruns, of the United States Navy, who is now present, and who requested me to read it. The paper is entitled, *A Paper on the Proper Time for the Exposure of Dry Plates*, and afterwards I propose to read a paper, hurriedly written by myself, relative to experiments made in the same direction. I hope you will not consider it egotism on my part to read what I have written, nor is the method of timing suggested altogether new, but I assure you it was written with the intention of calling out argument, in which all are invited to participate freely. It is a question of the most vital importance to us all.

Can a close approximation of the time of proper exposures be determined scientifically? The object of this paper is to give briefly a history of some personal experience in this direction. I would premise that the practice of photography is based entirely on variables, which is particularly unfortunate with the amateur, whose work is only occasional and with subjects constantly changing. He therefore learns nothing definitely by his previous work; his experience is of but little service to him, as he is constantly confronted with variables. To reduce the variables has prompted me to experiment upon the actinic effect of light. I have tried several plans, and finally adopted a very crude sensitometer, which, however, has served me very well. The sensitometer referred to is albumen paper freshly prepared for each day's work. This involves but little trouble or time. A strip cut from a sheet of albumen paper, say one inch by six, put in a jar containing the sensitising solution (nitrate of silver of some fixed strength) for an indefinite time, is drained and dried, and not to be fumed. Place the sensitised slip of paper between two flat pieces of wood bound together with rubber bands; pull the paper out to protrude, say, one-half inch. Expose this to the sun until it has blackened all it will, and call it actinised. Now pull out one-half inch more, expose it to the sun, and note the time. I find it convenient to stand back to the sun, or facing north, and place the paper on the ground at a distance of four feet from the point where I stand, and maintain this as a constant, and then wait until the newly exposed paper reaches the colour of the first, or is actinised, noting this time, which interval I will say is one minute. Suppose, now, I desire to take a copy of a picture in my room. I have here an ordinary plate holder so arranged that any portion of the sensitive plate may be shielded, while the rest may be exposed. In the dark room I shield all but the lower fourth part of the plate, I then expose it in the camera, say ten seconds, and take the plate to dark room, raise the shield, exposing this time two-fourths, or one-half of the plate. Returning to the camera, I expose ten seconds, thus giving twenty seconds to the first fourth, ten seconds to the second fourth, proceed the same with the third fourth, exposing ten seconds, then the fourth fourth, or the whole plate, exposing a few minutes with cap on, or it need not be exposed in camera at all. In the former, on developing, if the camera leaks it will show on the fourth fourth; in the latter, then the dark room lets in actinic light. Now the first fourth being exposed three times, each of ten seconds, or thirty seconds, second fourth twenty seconds, the third fourth ten seconds, the plate being developed will show which section was most favourably exposed. Assume this section to be the second fourth, or twenty seconds. We now arrive at the conclusion that when a piece of sensitive paper takes one minute to actinise, then say (Mr. R.'s) plate, registering sensitometer sixteen, requires twenty seconds for a proper exposure. On some subsequent occasion I desire to make a copy of a similar subject. Expose a paper the time to actinise is two minutes. I know that with (Mr. R.'s) plate, registering sensitometer sixteen, when the paper actinises in one minute it should be exposed twenty seconds, and from the following proportion the proper exposure of the plate of subsequent day is determined, namely: one minute to actinise is to two minutes to actinise, as twenty seconds (the trial exposure) is to the proper exposure, or forty seconds, which is the time to properly expose on the subsequent day. Therefore all that is necessary on the subsequent day is to focus and expose forty seconds, and we have a properly exposed plate. For outside work, using slow plates, follow the same procedure, but expose three plates. For economy use small plates. Make exposures of sensitive paper before and after the plates were exposed, to be certain the conditions did not change. Obtain the time to actinise the paper, and the time of the best of these plates. This gives a positive condition for that plate, and that character of subject. On a future occasion, by exposing a sensitive paper, the actinic condition of the light and the time of exposure is obtained by the law of direct proportion,

That is, the time of exposure of sensitive paper to a certain actinic effect on the trial plate is to the time of a subsequent exposure of paper to an actinic effect, as the time of proper exposure given by the trial plate is to four, or the proper time to expose the plate on a subsequent occasion, the character of subject being considered similar. The character of subject may be determined to suit the individual taste; for instance, a marine view, clouds, foliage, bright unlighted scene, or scene entirely in shade. If trial exposures are made for each, and carefully noted, there should be no difficulty, by reference, to obtain the time of correct exposures. For rapid work I place great reliance on the proper selection of the shutter spring. Its action should be uniform. It does not matter so much how fast it is, but that its tension should be constant. Fix the spring permanently. A rubber band is bad; it is deceptive, and subject to wide changes and irregularities. Graduate the time by the diaphragm, and not by varying the tension of the spring. In the trial exposures use, say, one-eighth, one-fourth, one-half inch stops. The areas of these are to each other as the squares of their respective diameters, and are respectively one-sixty-fourth, one-sixteenth, and one-fourth of an inch. The amount of light that passes through stops is directly proportional to their areas, hence the one-eighth-inch stop is four times faster than the one-fourth-inch, and sixteen times faster than the one-half-inch stop. Now, proceed with the plates. **INTERACTIONS.**—Expose the sensitive paper in the room on the wall directly in front of the lens. Make a trial exposure as explained under copying. Let the exposures be, say, half-hour apart, or what the experimenter may conclude as best. Note the time it takes the sensitive paper to actinise and the time of the exposure as given by the trial plate, and then by the rule suggested you can obtain the time for proper exposures in any other interior. In conclusion, I would recommend you to make a copy on the shielded system as applied in this plate holder, and you will be more than pleased to note the effect of the developer and the results. You will also see how much longer the zone of proper exposure is than you believed. You can tell what the actinic difference is, whether your windows are open or shut in the studio, and the range of time of any particular plate by which a proper picture may be secured.

Since Lieutenant Bruns's paper was written I have been experimenting further, and I have formulated the following as the result:—

To reach the maximum exposure any plate will stand has been one of the difficulties in the way of all photographers. When you have put your plate in the holder, the first question presenting itself is, "What stop shall I use?" Next, "How long an exposure shall I give this plate?" If you are in doubt you ask your learned and experienced friend near by, and he puts his finger alongside his nose, looks wise, examines the sky as if he were in search of a comet, and then coolly suggests: "Well I guess" (and it is all guess) "I'd give her, say, ten seconds." Now your own idea had been two minutes' exposure. If you ask four different persons, all of equal skill, they will "guess" at a variance of from fifty to one hundred per cent. Now how ridiculous this appears to be, and is. Here is a science based upon exact chemical laws, and yet we are constantly guessing. How to overcome that part of the guessing which relates to the exposure of a given plate has been the subject of inquiry and experiment by Lieutenant Bruns and myself, with the object of presenting the results for your information and discussion. Experiments made yesterday by us demonstrated that to actinise sensitised paper required one hundred and seven seconds. A Carbutt B plate (sixteen sensitometer) exposed in parts for two, four, and six seconds, on development gave best results and clear detail on that portion which was exposed for four seconds. Thus we had the two constants or non-variables for that kind of plate, they being one hundred and seven for the paper, and four for the plate. Now these results are to be utilised as the basis of all calculations for exposure of such plates, and the process of arriving at the correct time for exposure on some other day, when the light may be different, will be as follows:—Say next week, on a dull day, I wish to make a correct exposure of a similar plate. To do this I first expose a piece of the sensitised paper as explained. Say it takes five minutes to thoroughly actinise it, which is equal to three hundred seconds. Now I have learned that this day it required three hundred seconds to do what on another day requires only one hundred and seven seconds. I therefore make the figures to ascertain the required exposure to be given, to wit, as one hundred and seven is to four (these being the constants) so is three hundred to the required exposure, and the answer is thirteen seconds. So that yesterday I would give four seconds' exposure, and next day, as per example, thirteen seconds. With such experience as we have had, we feel satisfied this method is approximately correct. And I am certain, as experiment has proved, that the larger the constants the greater is the margin for correct exposure of the plate when taking a picture. That is, if the constants are ten times greater than those given, say one thousand and seventy seconds and forty seconds, the chances of correct exposure are increased in that ratio. An experiment made to-day with a new lens and camera showed that it only required ninety seconds to actinise the sensitised paper, and that a Carbutt B plate exposed seven seconds with the smallest stop (being only three-thirty-seconds of an inch in diameter) gave the best negative. The two figures being used as new constants, a further experiment was made by exposing the sensitised paper in the shadow of our working room. After exposure of eighteen minutes and forty-two seconds, the paper showed partial actinisation. As time was pressing (at four o'clock p.m.), a piece of paper was taken into the sunlight and was allowed to actinise up to an apparent similar extent, which required twenty seconds. At the same time a fresh piece of paper required two minutes in sunlight to become fully actinised. It will therefore be noted that the piece of paper exposed in the room, which had been partially actinised, if taken into the sunlight would have reached actinisation in two minutes, or one hundred and twenty seconds. And as it required two minutes to fully actinise, it had been exposed to within sixteen and two-thirds per cent. of complete actinisation. Multiplying this partial actinisation of the paper (say 16·67) by six, we show that it would require about one hundred and twelve minutes, or six thousand seven hundred and thirty-two seconds, to actinise in the shadow of the room. Again using these figures, we show that as ninety seconds required to actinise in full sunlight is to six thousand seven hundred and thirty-two seconds, so is the time of proper exposure determined this morning, say seven seconds, to the time of proper exposure this afternoon in the shadow, which is eight minutes and forty-four seconds. To summarise these figures, we may say that the simple sensitiser adopted—that is, the silvered paper—will give a very near proximate of the proper time for exposure of any given plate when taken in connection with the standard time of actinisation, which we call a constant, and the exposure of the plate mentioned, as in the shadow of the room, was done without any other than this simple means. There need not be any doubt as to the use of the stops; one single stop will do for all exposures, when once this constant is obtained with any one of the series. So far as we are able to judge at this time, we prefer using the pinhole stop, which has given the results mentioned above. If any man ask, "Well, what of all this?" we can answer that it is an approximate method of arriving at the proper time for exposure of a given make of plates, and that too without any "guessing." In presenting this for your consideration we are not unaware that others have experimented in the same direction, nor that the omissions on plate and sensitised paper are chemically different, but we are anxious to broach the whole subject for your consideration, hoping it may lead to investigation and some useful result.

Mr. FRISBIE: You mean by adopting the idea suggested in your paper you can get the exact time to expose your plates?

The PRESIDENT: Yes, any time of day. This paper which I have just read involved an immense amount of figuring, and I do not conceive that there is any possible way by which this could be put in any other shape than it is. Lieutenant Bruns and myself read it over, and it is as brief as it can be stated.

To arrive at these figures was a matter of considerable trouble. You have no idea of the amount of labour involved in the work. You don't have to expose a plate every day. You go out and take a picture to-day for instance, and find that a clear brilliant sunlight actinises paper in a given time. You may take that time as the basis for several days' work.

Mr. ATKINSON: Suppose there is no sunlight.

The PRESIDENT: Then you do not expose the paper.

Mr. ATKINSON: Then you cannot tell anything about it. I merely say that because for four years I used that very test in printing carbon prints. I had a small negative with a printing frame marked from number one to number twelve, and there was a slip of sensitised paper placed in that, and there have been times when I got fair negatives, but I consider it very unreliable.

The PRESIDENT: In regard to the constant (by which I mean the non-variable figure) upon which all this is based, the sensitised paper is exposed when the sun shines and you get a figure, which, as I say, lasts you all the year round. It is immaterial whether the sun never shines again. You have got nothing to do with that. You do not have to ascertain a new constant, you use the same one. But you expose a piece of sensitised paper to the light, whatever that light may be, and that gives you the second figure in your problem by which you arrive at the third.

Mr. ATKINSON: If you are testing bromide with bromide of silver, or chloride with chloride of silver, that would be a different thing, but you are testing one thing with another here.

Mr. RIPLEY: What do you say about the gaslight? I can take a picture by gaslight. Dry plates are made with bromide of silver, and the condition of this is in an entirely different state in the gelatine plate than in the albumen film, and is affected differently by the light and by different kinds of light, and I say that I can get a good picture in half the time by gaslight. You cannot blacken the albumen paper by gaslight.

Mr. NEWTON: It would undoubtedly be a valuable acquisition to photographers, whether professional or amateur, if you could come into the possession of some infallible guide in reference to timing any particular plate. The experiments named I tried quite a number of years ago in a little different way. I made a little round metal cylinder about three inches in diameter. It shut together, allowing for the roll of albumen paper a half an inch wide to come out of a little thin slot; and, instead of depending on the light to colour the paper, I painted the colour, pulled the paper out of the slot, and painted the colour which albumen paper would come to in a given time, and my experiments with the albumen paper showed me satisfactorily that it was not reliable, especially in different coloured lights. You take an orange coloured light, and it will act upon the chloride of silver about as quick as a white light. That is, any professional photographer who is printing on a day when the sky is clear and has a yellow light, will print his prints as quick as he would if it was a white light, and the action of that light on the bromide of silver would require at least double the time; and again, when it begins to be late in the day, say five o'clock this time of the year, it is not a very difficult thing to make an instantaneous picture, but it will take a pretty long time to make a print on a piece of chloride of silver paper. Then, again, there will be a little variation in your paper unless you try it every day, and your standard would be likely to vary the sensitiveness of your chloride of silver paper. It is not generally known, I suppose, that some acids are an accelerator and increase the sensitiveness of the chloride of silver. But I have made experiments in that direction, and I took what we call plain paper (starched or ordinary plain paper) and sensitised it. I once had occasion to make a picture that took all day to print it under a leaf. I wanted to get the anatomy of a leaf, and it was a dark green, and I had to expose that sensitised paper all day, and the next day I sensitised some paper, and after the wet had got off the surface of it I laid it, back down, on a five grain solution of citric acid. Now that increased the sensitiveness of it at least six times, and I could make the same print in two hours that it took me all day before to make. And whether the ordinary albumen paper is fumed would make a great difference in the action of the light upon it. In the exposure of a plate my rule is to over expose always, that is for a normal developer, and then I commence very weak, very low down. I make up my developer of the ordinary strength, and I take a little of it and put it in water and commence very weak, and I always have it a sure thing if I have got the right exposure. I have a couple of negatives—I would have brought them along if I had thought of it. One of them was exposed two seconds and the other twenty seconds, and any one looking at them and examining them would say that the two seconds' one was the one that was longest exposed, simply by the way that they were developed. One of them was exactly as good a negative as the other. There is a great deal to be said on developing negatives, and I am not sure that everybody will ever come to making one as good a negative as another. There are constitutional impediments in the way. You cannot educate some people so that they know a good negative when they see it, and they never will succeed except by chance in making a good negative. Now it is one thing to observe and another thing to perceive. I had a bookkeeper once in my employ who could not tell blue from green, or red from yellow, or anything of that kind, though he was an excellent draughtsman and a fine musician. His ear was all right, but he could not discern the difference between colours. I might say that the colour of that book, for instance, is green and the other side of it is blue, and I would turn it over for instance, and ask him which is which, and he could not tell me. He would say that there was some difference, but which would be the green and which would be the blue and which would be the yellow he could not tell. You could not educate that person; and a person that is undertaking to develop a negative after the plate has been exposed has got to have the faculty of perceiving as well as of observing. That is quite essential. Of course a person can by perseverance educate himself and overcome a great many of these difficulties. Now I had a gentleman that used to come to my house—a scientific gentleman, too, he was—quite a number of years ago when I was making collodion emulsion, and I gave him the formula and he made it, and he came to my house two or three times a week and begged me to do it because he could not make a negative that was good for anything. It was all fogged. He said that he had followed my directions exactly, and as I had given them to him; nevertheless, he said, the plate would be fogged. He

would take his emulsion and make a negative, and would come back the next day and bring me some of his results; they were utter failures. But he was inflexible. He stuck to it for six months, and he finally overcame all those obstacles, and can make as good a negative to-day as anybody. Now, another person would do that same thing after trying three times. There is a difference between people. One man has a good deal of a job on hand when he undertakes to make a negative, and that work to another man would be a very light job. The same as one person is a good mathematician, and it don't bother him at all to solve a problem, while another is a good chemist, and another is a good musician. You cannot make a chemist out of a musician, or a musician out of a chemist; and it is just the way with an artist. You cannot make an artist out of everybody, and a person, in order to be able to make a good picture, has got to be an artist as well as a chemist.

Mr. SPAULDING: I think Mr. Ripley and Mr. Newton have come practically to about the same conclusion, and it seems to be a very reasonable one, though I have not experimented on it. If I had a weight of 300 pounds to move across this room, and I had another weight of 3000 pounds to move across this room; supposing I could move the 300-pound weight across the room in five minutes, how long would it take me to move the 3000-pound weight across the room? Why, I could not move it at all, and it seems to me, Mr. Chairman, that this question of the sunlight has about something of that sort of thing to do in this case. It has been said that a great many of our plates contained both the iodide and bromide. It may be the sunlight when removed to a certain degree, as it is on dark days, for instance, cannot do work at all. If we believe the philosophers who tell us about the atomic theory of matter, these molecules are made up of certain atoms, and the sunlight has got something to do with the atoms of that molecule. There are a great many people who believe in the physical theory, and there are a great many people who believe in the chemical theory. But the sunlight has got something to do with the atoms of the bromide or iodide; it has got to produce a certain change in the atomic condition of the molecule, and whether it can do that depends on the strength of the sunlight and also on the weight of the atom that has got to be moved. Now, Mr. President, it might be that what you have suggested in your paper is quite available within certain limits, but it would not be available under other circumstances, and I do not believe, with all due deference, that it is well to claim too much for it.

The PRESIDENT: Well, of course, we made this test with a view to having this matter brought up for discussion here. We are not infallible, as you are probably well aware; but, acting on the theory which I have suggested, and, after figuring elaborately and carefully, you see the conclusion which we reached, and here is the negative made upon the basis of those figures about five o'clock this afternoon. We simply put the plate holder in its place, exposed it by the watch, and there is the negative.

Mr. NEWTON: In some instances some plates might be exposed twice as long as others, and by manipulation, by which I mean the development, you cannot tell which was exposed ten minutes and which was exposed five minutes, they would be so much alike.

The PRESIDENT: I quite agree that much can be done in developing. As an example of what you just said regarding development, by which I mean the manipulation of the plate in the developer, to bring about a result that nobody expected except the man who manipulates, I made a lantern slide for a person who is here now, and there being seven persons present, and several of large experience, I asked them to say how long exposure I should give the plate. They looked out of the window, looked wise, and varied between ten seconds and ninety seconds. We took the average of them, and made it thirty-five seconds. After exposure of one plate for ten seconds and the other for thirty-five seconds, I went in the dark room and developed both of them, and after they were developed the most learned photographer among them all picked out the one that had been exposed the least and said it was exposed the longest. It only shows you what the opinions are worth as a rule. How was it done? Why, in the development of the plate. I manipulated that plate; I juggled that plate, as you say, into being that which it really was not, that is, giving it strength and density; that which would never have happened except for being handled very carefully in the developer; and the plate which had been exposed the longest I handled very carefully, and kept back the development, and did not hasten it. In other words, I juggled that too, and the result is I got two excellent negatives.

Mr. RIPLEY: This question of over exposure and under exposure has been discussed quite lengthily and intelligently in the English papers for a year or more back, and a writer said that there was a very great question as to whether there was in fact such a thing as over exposure and under exposure; and I want to say that the article was a very sensible one, and he came to the conclusion that over exposure and under exposure depended altogether on the developer that was used and upon the man that handled it. Take our modern dry plates, both of the English and American manufacture, and there is a great deal more latitude in them than we are inclined to think. We make an exposure and throw our normal developer on it, and if it comes out right the exposure is correct, but a great many of us take no pains at all to decide as to whether it is going to be right or wrong, and if we think it is going to be wrong we take the proper steps to save it. With intelligent and careful workmanship you can expose two identical plates the extreme of short and over time and still secure good negatives, and you can not tell the difference between them, and it is hard to get a test that will tell what over and under exposure is.

The PRESIDENT: What have you more definite to say about this method, or theory, that has been proposed? Have you got anything very strong to say against it? If so let us hear it. What is your objection to it, beyond what you state? In my opinion you have not hit the nail on the head at all, if you will allow me to say so.

Mr. RIPLEY: Why, we prove it is non-scientific, and we prove that it is useless.

Lieutenant BRUNS: What is there, I ask, in photography that you know is scientific? Is there anything that is scientific in the art?

Mr. RIPLEY: There is a good deal in photography that is scientific, but it has never been found out. Take the best chemists of the world and no two of them will give you the same reason for the same result. Why collodion sen-

sitised to-day to take a photograph will give you a certain result, and that certain collodion kept a month will give you a totally different result in the way of producing a picture, is something that nobody can tell. We know it does do it, but we cannot tell why. I may mention that as one instance. Photography, as a science, is very largely tentative, and the relation of cause and effect in it is very little understood. There is lots of science in it but we don't understand it.

Lieutenant BRUNS: I agree that there is lots of science to be found in photography. I had studied up the subject of photography, the theory of it, and the chemistry of it, and I thought I knew something about photography, and I thought all I would have to do would be to come around here and say, "Smith, give me your developer," and that was all, and point to the camera and it was done, and I believed it was scientific, and if photography is an art it is based on the laws of science, and if it is based on the laws of science it is invariable and we can find the laws. I could not find any laws, and I said to myself, "I cannot take a picture until I know I will take a good picture. I do not know anything about photography; practically nothing, absolutely nothing. There is nobody in this Society but who can give me the most rudimentary instructions, but I will know something about it. I am determined about that. I know if I take the time I can make as good a picture as anybody else, but I might spoil three or four boxes of plates in getting a picture; but that does not make any difference. I get the picture all the same." And one of the principal reasons that has urged me to try to arrive at some conclusion in obtaining a proper exposure was this, that if I should by guesswork go out and get a beautiful picture, and my friend should come to me and say, "That is beautiful," I would say, "Yes, it is beautiful," and he would say, "How I would like to have you come and take my beautiful lawn, and make me another beautiful picture like that." I would have to say to him, "It is beautiful, but it is all guesswork, I do not know how I did it, but I got it."

Mr. WILLIAMS: The criticism that I make of this paper is, that I do not know how to apply the principle which you have brought out to any practical outdoor work. I have no interest in copying black letters on white paper. The subjects that I take with my camera are, we will say, like that print over there, with the cows under the trees. Now one of those cows is a white one, and some are dappled, and the white cow is fully exposed, and the red cow is not fully exposed. The difficulty in that picture, I suppose, is over exposure. It is generally so in all pictures. I would like to know how it is proposed to apply that to a landscape, or subject which has objects in the shadow and objects in the sunlight. I would like to know how it is going to help the artist or the photographer to judge what exposure is necessary to get the proper graduation of lights, and how to bring out the details and shadows successfully, and in that way make an harmonious picture. In my practice, and I do not claim to be proficient, the only way I can do that is in the developer.

Mr. NEWTON: There is another objection that has been just alluded to. In using that paper, if you have three or four different lenses (I generally take five, six, eight, ten, twelve, and fourteen-inch focus), and I make a picture with a six-inch lens, and I use another lens of twelve or thirteen focal length, of course I have got to give a longer exposure to the same object, and so your test would not apply to both in a case of that kind. While you use different focal lengths you increase the exposure by the focal length of the lens you are using. I hardly ever, if I am going out to make a dozen pictures, make them all with the same lens, and expose according to what I think right. Now to illustrate. On Election Day I went upon the Bronx River, and the ordinary exposure with a six-inch wide focal tube was two seconds with the smallest stop, and with the sun pretty well on my back; and then I turned around and made a picture down the river instead of up, and I gave seven or eight seconds where the shadows were heavy; and the last one I took, which was directly against the sun (which was shining against my tube unless I shielded it), I gave thirteen seconds, and while I was looking the other way two seconds would have been plenty; and none of my pictures were over exposed and none of them under exposed. I made good negatives of all of them. The thirteen-second exposure was as good as the two-second exposure, although one was a longer lens than the other. I will say just a word more while I am talking in reference to the action of light upon the sensitive film, and the theories that have been supposed to account for the phenomena in the main, that actinism was a property of light resident in all waves of light. That was not Becquerel's theory. But latterly that has been adopted with the exception of one chemist, who several years ago promulgated the theory that actinism had nothing to do with it; that it was purely mechanical. And those who recollect his theory, and the experiments that were made, will recollect that he proved to his own satisfaction the correctness of that theory; they were long, and extended, and very ingenious. He claimed that the force of the light impinged on the sensitive film made the image, and that chemical actinism had nothing to do with it. Now the other theory, that it is actinism and that it is resident in the light. In regard to that, in some experiments we have seen lately in some theatres, in reference to colouring the film, so as to photograph coloured objects, where you transpose all of that, you introduce a red screen under certain conditions, and you get more actinism on reds, and the greens, and the yellows, than you do on the violet and blue. Now where are you coming out? Where are you going to land? If that is so, the old theories in reference to the actinism being mainly in the violet seems to be on a weak foundation. Now light acts differently on different things; that is, in reference to mineral salts. You know, most of you, I suppose, that Professor Draper, as long ago as from 1843 to 1846, by a long series of experiments, showed that the yellow light had more actinism in it than the violet one, which acted on vegetable fluids, and right the other way when on mineral salts.

Mr. ATKINSON: The whole question resolves itself into this: that you take an over exposed plate—a man with a thorough knowledge of the art, with proper use of the developer, can accomplish something; but with an under exposed plate the picture is not there, and no amount of knowledge of development will produce it.

The PRESIDENT: You can find a gentleman in this room that will dispute that proposition; he maintains that an under exposed plate can be made as good as a plate that has been over exposed.

Mr. ATKINSON: That is dodging the question. If the plate has been under

exposed can it be made as good a negative as if it had been over exposed?

Dr. PIFFARD then stated in substance that Mr. Ripley said earlier in the evening that a plate can be exposed sixty seconds longer than it ought to be exposed and then be made to produce a good picture.

Mr. FRISBIE: Dr. Piffard hardly seems to arrive at the question. He assumes there that a one second exposure would have been a normal exposure sufficient to give you a good negative with well-judged developing, and the sixty seconds exposure, which would in some cases be an over exposure, that you would get a good negative even at that great length of time. But the question is, Can you get a good negative from an under exposed or a plate that has been very slightly exposed to the action of the light? I should say no, because the light has not had an opportunity to act upon the plate at all. It has been virtually in the dark in some parts of it. In the high lights you might be able to get a well developed negative, but in the dark shadows you get nothing, no matter what chemicals or strength of chemicals you use.

Lieutenant BRUNS: I want to answer two questions in regard to the sensitised paper. Of course, all my remarks are purely theoretical, as I have said before, because I have no practical knowledge of photography. I never took an outside picture in my life, and I do not know how to develop; but I premise my statement that I have some knowledge, theoretically, of photography. A gentleman here this evening has remarked something about taking an outside exposure in which he includes distant as well as near objects. He finds fault with the sensitive paper because it does not correct the condition that is universally recognised, that distance, as a general rule, does naturally over expose, and nearness under expose; but that should not fall to the lot of the poor sensitive paper. It is a condition that happens anyhow. It is a condition that has got to be contended with in some other way. It has got nothing to do with determining the time of exposure, and I believe Mr. Newton made some pertinent remarks in reference to the difference in the focal length of lenses. It is true you could not determine a constant where you would introduce a new condition under which that constant was determined. We determine a series of constants with certain lenses, and, if necessary, with a certain number of lenses; but, if you wish to change it, your constants are to be determined for each particular lens.

Mr. RIPLEY: A great deal has been said on this subject since the reading of the two papers, and I have remarked that photography as a science is largely tentative. The most that we know of a certainty in regard to photography, and the action of the light on the chemicals has been found out tentatively—that is, by experiment—so that when I called this method of determining the time exposures as non-scientific, I mean that the action of light on chloride and bromide and salts does not act in the same way. It depends on the condition that that salt is in, and I call the method unscientific, and, judging of your deductions from the same standpoint that we judge of what has been found out in photography, and the remark of Lieutenant Bruns that it is non-scientific, inasmuch as he has confessed that it is pure theory, corroborates my own view. And the remarks that have been made here in regard to the latitude of exposure which we have in the practising of our calling, and manipulation of the developer, and other means, and the cases that have been here cited, all show the latitude to be so tremendous, that it clearly and distinctly and tentatively shows the idea to be useless and not worth the trouble that it entails to put it into practice. I think that sums it up in rather a small nutshell.

The PRESIDENT: Notwithstanding all that the gentleman has said, and I have great regard for his views, I cannot see why—if I have a brand of Ripley plates of sixteen sensitometer, why, having tried one of them, and found by actual exposure that it takes seven seconds to get a good negative in a light where my paper sensitometer requires sixty seconds to actinise—why I have not got a good guide to know how to expose the next plate when the light conditions have changed with that same batch of plates.

Mr. RIPLEY: At that moment, on the same subject and all the conditions being the same, except possibly the quality of the light, do you mean to take into consideration those conditions?

The PRESIDENT: Yes, take into consideration that it is the same plate, but the light is changed. Now under those circumstances I use my sensitised paper and determine the right exposure.

Mr. RIPLEY: I claim that the light will change so that it will not affect your actinometer, when the plate will be affected. I have seen daylight so weak as regards affecting your actinometer, that it would show nothing in a long time when a bromide plate would be affected very quickly.

The PRESIDENT: You don't answer my question.

Mr. RIPLEY: Put your question exactly so that I can answer yes or no to it.

The PRESIDENT: Say, for instance, that one moment the sun is out and the next moment the sun is obscured, and I want to take a good picture. I hold my sensitometer out, and it takes that paper twice as long. Now what shall I do when the sun is obscured five minutes after I have taken the first picture? Won't my sensitometer be a fair guide for me?

Mr. RIPLEY: No, sir; it will not be a fair guide, because it will not give you the indication. It will give you the direction which you may work in, which direction may be or may not be reliable.

The PRESIDENT: Has anybody anything more to say about it?

Mr. WILLIAMS: I would like to know how the ideas which you have suggested in your papers are to be practically applied. In timing a picture there is no trouble in getting your high lights in the sunshine, but the shadow is the trouble. If you don't get detail in a shadow it will be a big black blotch. How is it proposed to apply the actinometer to a case of that kind and give us some help?

The PRESIDENT: The idea is put forth as an approximate method of arriving at a more proper exposure by knowing the force of the sunlight. This proposition is not perfect. We have experimented with it, and so far as we have experimented it has worked successfully, and we knew if we brought it up here for discussion that we would be knocked right and left, and we knew in the end there would be a discussion upon the development of plates, that would be interesting anyhow. Nobody can tell exactly to a second how much exposure to give, and no instrument can be devised because of the varying condition of the plates, and the surroundings are such that it would be impos-

sible; but we cannot conceive of any nearer way of arriving at a correct exposure than by ascertaining the exposure by the power of the light, and not guess at it. A man in taking a picture naturally looks up at the light he is going to have, and he makes his exposure. The method suggested certainly gives him a kind of approximate, and a very close one it appears to us; but you, gentlemen, must not expect too much from us. We cannot answer you positively in regard to the matter. We are, as I stated heretofore, humble in our pretensions, and you must deal kindly, and do not sit down too hard upon us.

Mr. BEACH moved that the Committee on Dry Plates take this matter up and report at a future meeting.

The motion was carried.

Mr. FRISBIE: There is one question I would like to ask. I do not know whether any one has ever investigated in that direction or not, and that is, After a plate has been exposed and the light has affected it, whether it is possible to apply any solution to that plate which would make it non-actinic, and yet the plate be taken out in the broad daylight and with some developer cause a deposit of the oxide of silver?

Mr. NEWTON: You can take an ordinary plate and let it lay in the light of your studio a week and make a good negative on it.

Mr. FRISBIE: What I refer to is this: I take my plate and expose it to the action of the light in the camera and then soak it in some solution which will have the property of preventing any further action of light on that plate when it is exposed to daylight again, and yet after that be able to bring out the image by some developer.

Dr. PIFFARD stated in substance that he had heard of such a thing; that Mr. Roche had shown him some plates which Mr. Roche said were developed in the daylight, and said that he could take a plate and make an exposure on the plate, and would then take it in the dark room and do "something" with it—Mr. Roche didn't tell him what he did with it—and would then take it out in the daylight and develop it.

Mr. NEWTON said he would take a plate that had been exposed to the light for a week and put it in a solution of nitric acid and bromide, and gave the proportions, and restore it to its normal condition and make as good a negative on it as though it had not been exposed at all. There is no question about that.

The meeting afterwards adjourned.

Correspondence.

Correspondents should never write on both sides of the paper.

JULY MEETING OF THE PHOTOGRAPHIC SOCIETY OF FRANCE.—VALUABLE DOCUMENTS FOR THE HISTORY OF PHOTOGRAPHY FOUND IN THE COLLECTION OF THE LATE M. BAYARD BY M. DAVANNE AND PRESENTED TO THE SOCIETY.

The Photographic Society of France held their monthly meeting on Friday evening last, the 1st instant, M. Davanne in the chair.

That gentleman informed the members present that he had just returned from Nemours, where he had been invited by the heirs-at-law of our late member, M. Bayard, in order to seek if peradventure among the photographic objects and proofs in their possession some might be of value to the Society in an historical point of view; if so, the heirs-at-law would be most happy to present such objects to the Photographic Society of France. M. Davanne then opened a cardboard and exhibited the contents.

1. A collection of photographic prints pasted on cardboard. These proofs were exhibited to the public on the 24th of June, 1839, in the "Salle des Commissaires-priseurs," and that for the profit of the victims of the Gandeloupe. These images were examined with the greatest interest, they being over forty-eight years old. Time has laid its grasp upon them; they have faded and turned yellow, but the images are yet visible. By an article in the *Moniteur* of the 21th of June, 1839, we can learn that M. Bayard exhibited photographic proofs on paper one month before Daguerre published and gave his process to the world. The cause why the name of Bayard has not become a household word like that of Daguerre is because M. Bayard was very timid and modest in the extreme. Nevertheless, the process of Daguerre is, at the present day, set aside, and paper proofs now predominate. 'Tis true that the same system which he employed is not adopted; but he certainly must have the honour of having printed photographically the first paper proof. His process will rank him among the inventors of photography, and his name will be found beside those of Niepce, Daguerre, and Talbot.

M. Davanne then exhibited the second lot, consisting of several Daguerrian plates of a large size, and very well preserved. M. Davanne drew the attention of the members to the fact that such large plates were now very rare indeed.

3. An instantaneous proof of the Place Vendôme, representing the procession of the *Bœuf gras*. This was naturally obtained upon a collodion film, as at that time the gelatino-bromide process was unknown. This proof can well bear comparison with the generality of instantaneous views made even at the present day; on this account they created a certain amount of surprise.

4. Two or three negatives of M. Bayard upon the "Siamoise" plan—that is to say, the same person represented twice shaking his own hand, painting his own image, fencing with his *sosie*, &c.

5. Several proofs on paper obtained by his first process, which consisted in coating paper with silver chloride, then exposing it to the sun's

rays until it became as black as possible: the paper was then floated upon a solution of iodide of potassium, the paper thus prepared was placed in the camera, the light acting upon it bleached it more or less; the result was an exact copy of the object to be reproduced.

A vote of thanks was given to the heirs-at-law. PROF. E. STEDING,
59, Rue des Batignolles, Paris.

PLATES FOR PHOTO-MECHANICAL WORK.

To the EDITORS.

GENTLEMEN,—Referring to your leaderette in the last number of the *JOURNAL*, "Collodion *versus* Gelatine," and the suggestion contained therein, we beg to say that we have for some time past made special plates for photo-mechanical work, which yield negatives similar in character to collodion negatives.

We have a steady sale for these specially prepared plates, and have frequently received flattering testimony from gentlemen who employ them for photo-mechanical work. Herewith we send negatives for your inspection.—We are, yours, &c.,
MAWSON & SWAN.

Newcastle-on-Tyne, July 4, 1887.

[The negatives received leave nothing to be desired.—EDS.]

OUR FATHERS WHO ARE IN THE SOUTH KENSINGTON MUSEUM.

To the EDITORS.

GENTLEMEN,—Your correspondent, Charles Mason, appears to have made inquiries concerning the Fathers of Photography everywhere but in the right place. If he will take the trouble to go to the South Kensington Museum, Science Department, West Galleries, he will see my collection of "Our Fathers," including Daguerre, Rev. J. B. Reade, Fox Talbot, Mungo Ponton, Sir John Herschel, and Dr. Alfred S. Taylor, with a tablet underneath each containing the dates of their births and deaths and a brief record of what they did for photography.

Mr. Mayall, Bond-street, possesses a portrait of Daguerre; Messrs. Maull & Fox, Piccadilly, a negative of Rev. J. B. Reade; H. H. H., Cameron, Gothic House, Mortimer-street, W., of Sir John Herschel; and the *Photographic News* published portraits of Daguerre, Fox Talbot, and Mungo Ponton, a few years ago.

Portraits of Niepce, Robert Hunt, or Frederick Scott Archer, I never was able to obtain, but think it is to be regretted that they are not obtainable. The late Mr. Silvester possessed a portrait of Archer, and once promised me a copy, but I never received it. There are many other names among the early workers, also, whose portraits would be very interesting at present and in the future if they could only be had, and I think it would be worth while making such a collection and placing them where they could be seen at any time by those interested in photography. I handed my collection over to the Lords of the Committee of Council on Education for that purpose, and I think it very desirable for others to do likewise.—I am, yours, &c.,
J. WEAVER.

11A, Berners-street, W.

PHOTO-MICROGRAPHY.

To the EDITORS.

GENTLEMEN,—My attention has been called to a communication from "Procella" in your issue of the 3rd instant, in which the writer, after very earnestly insisting upon the necessity of an exact coincidence in the registering of the focussing screen and sensitised plate in photo-micrography, goes on to say: "If it were possible to remove the screen from the frame and substitute the sensitive plate for it, photo-micrography would be made a much simpler affair than it now is."

From the fact that the same idea is advanced in "Procella's" article in *THE BRITISH JOURNAL OF PHOTOGRAPHY* for the present year, it is evident he has not read any of my communications on the subject heretofore published in *THE BRITISH JOURNAL OF PHOTOGRAPHY*, and I trust that I may therefore be pardoned if I repeat a portion of same herein.

It is quite evident to all workers in this direction that no surface can be placed upon a sheet of glass by grinding—of sufficient fineness to serve for accurate focussing—with even moderately high powers. In my search some years since for a suitable medium for this purpose I found that an ordinary gelatine plate, which had been exposed to a flash of white light, developed to a slight smokiness without density, washed and fixed as usual, and finally bleached with a solution of bichloride of mercury, made so perfect a focussing screen for this purpose that nothing further could be desired. I claim no originality in this application of a dry plate, as my attention was called thereto by a writer (whose name I have forgotten) in one of the English journals. But my method of using it was original, and, I think, fulfils "Procella's" requirements most completely.

My camera is provided with the ordinary focussing screen of fine ground-glass, which is hinged so as to drop out of the way when the plate holder or "dark slide" is to be attached to the box. This ground-glass screen is only used for securing an even illumination of the field and arranging the object in its desired position thereon. These preliminaries

effected, the usefulness of the ground-glass ceases, and it gives place to the prepared gelatine plate, which is used as follows:—

The plate holder is *single*, with slide and back both entirely removable, leaving only a framework, which is placed in position on the back of the camera and secured by a spring catch. The bleached gelatine plate is now put into the framework (film side toward the object), where it occupies identically the same position as will be subsequently filled by the sensitive plate. A focussing glass is applied to its back, when it will be found that the most delicate adjustment can be made quite as readily as with the ordinary table microscope. The proper focus secured, nothing remains to be done save to remove the frame from the camera, to restore the slide and back, and insert a sensitive plate in the dark room, when the exposure can be made with an absolute certainty that focussing screen and sensitive plate "register" exactly. Should "Procella" or any other of your readers desire more precise information on this subject I shall be pleased to supply it to the best of my ability.

I also venture to correct an error into which "Procella" has fallen in his article in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC previously alluded to, in which he says that the photo-micrographic camera of Bausch & Lomb is constructed to be used *with* an eye-piece. Having owned one of these cameras for some years, and inspected several others, I may say that they all were made to use *without* an eye-piece, and that no possible provision for the attachment of the latter to any of them had been made.—I am, yours, &c.,

W. H. WALMSLEY.

De Lancey-place, Philadelphia, June 19, 1887.

Answers to Correspondents.

NOTICE.—Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a NOM DE PLUME as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

W. WALLIS.—We have forwarded your letter on to Mr. Barrett.

M. B. (Heris).—So far as we are aware, no one keeps dry plates on patent plate in stock. No doubt any maker would supply them on that kind of glass to order if required.

E. SHAW HARPER.—1 and 3. It is strictly against our rule to pass an opinion on the merits of different makers' goods.—2. There is no patent for the diaphragm. It is a very convenient form to employ.

J. ALPHANT.—Photographs can be taken in the camera without a lens. All that is necessary is to have a minute orifice in place of the lens. This system of working has no practical value, still it is a possibility.

S. W. H.—If the material with which the mounts are printed is really silver the particles becoming detached will not injure the photographs. The only way of ascertaining if it is silver is by a chemical analysis.

NEWLYN.—The yellowness is due to imperfect fixation. If the bath was the strength you say, they must have had but a brief immersion. We imagine there must be some mistake with regard to the proportion of hyposulphite of soda used.

R. MERRY.—Before commencing to repolish the cameras the dirt should be carefully removed with soap and water. French polish really for use is supplied by most oilmen. It will be better for you to purchase it than to compound it for yourself.

OPERATOR M.—We scarcely understand your query. By "portraiture" do you mean lighting and posing the sitter? If so Bigelow's *Album* would possibly answer your purpose. It is out of print, but you will doubtless be able to obtain a copy by advertising.

J. A. N. says he expects an order to take some very large photographs shortly, and asks if there is any one who lets large cameras and lenses out on hire.—No doubt some of the dealers in second-hand apparatus will supply what our correspondent requires on loan. Let him try Messrs. Sands & Hunter or Mr. Morley.

C. G. TURNER has an old oil painting to copy which is very dirty, and asks whether it will be safe to wash it with water.—The picture may be sponged with clean water with safety. If water alone will not remove the dirt, a little curd soap may be rubbed on the sponge. The soap must, of course, be thoroughly washed off before the painting is dried.

W. SHEPARD writes: "I am making a wooden portable studio, eighteen feet six inches by eight feet by seven feet six inches high at eaves. Will you please advise me in your next issue as to quantity and position of glass for same?—Let our correspondent make four feet six at either end opaque and have all the rest glass. Thanks for the cutting. The idea is absurd enough.

RURAL.—As no less than three brands of plates give fog in your hands we suspect that the fault rests with you. Possibly your dark room light is not sufficiently non-actinic. See to your window if you employ daylight. For taking groups of children indoors employ a portrait combination, so as to secure rapid exposures. We imagine our readers would not care for an article on the subject you mention.

INQUIRER (Leeds) wishes to know how unmounted prints can be prevented from curling up. He says those issued by some of the large publishing houses have not this tendency to the same extent as his own have.—If the prints be rolled with a very heavy pressure on a burnished steel plate they will have but little tendency to curl afterwards. Squeezing the print while wet on to a glass plate and allowing it to dry will also remedy the evil. Of course the glass must be rubbed over with French chalk to prevent the print from adhering when dry.

A. E. SMITH sends a print from a wood block on common paper, which has been hanging in his studio for a couple of years, and calls our attention to the discolouration of the paper. There is nothing at all unusual in this. Most common paper made from wood fibre will show a marked change with only two or three days' exposure to the sun's rays, particularly if it be kept in a moist atmosphere. The example sent has discoloured badly.

G. MONRO complains that when he attempts to mount photographs with gelatine he cannot succeed, owing to the gelatine setting before he can coat the print all over; hence, when it is laid on to the mount it is not even, owing to the lumpiness of the gelatine. Coignet's gold medal gelatine has been employed.—The gelatine named is quite unsuitable for mounting prints, for the reason that it sets so quickly. The best kind for mounting purposes is one of a poorer quality, such as that known as soup gelatine. Messrs. Nelsen, Dale, & Co.'s "No. 2 Soluble" is a very good gelatine for mounting photographs with. It is free from acid and does not gelatinise rapidly.

J. L. R.—1. Unless the spots can be seen before the plates are exposed, they are no doubt produced by air-bells adhering to the film while being developed.—**2.** The fogged appearance in the centre of the negative is caused by flare spots in the lens. It may be cured by altering the position of the stop.—**3.** A formula for the potash developer will be found on page 311 of the ALMANAC.—**4.** Yes, by adding a small quantity of tartaric acid, and exposing the solution to sunlight. But, on the whole, it is better to use the solution freshly mixed.—**5.** The green colour is due to the print being under exposed. With a longer exposure, and a shorter development, the colour would have been much improved. Thanks for kind offer.

C. A. TIMMINS asks: "Would you, in 'Answers to Correspondents,' give me a few practical details how to obtain enlargements on platinotype paper? I have two lenses, both Ross', one rapid cabinet lens and rapid symmetrical 8×5. I want to enlarge from quarter-plate to 12×10."—In the first place, an enlarged negative is necessary. This is obtained by making a transparency from the original, and then from that making an enlarged negative. From this the platinum print is made in the ordinary manner. Either lens will serve for the enlargement; the shorter focus one will be the more convenient to employ. By the aid of the solar camera direct enlargements may be made by the platinotype process. But we presume our correspondent is not the possessor of one.

W. A. M. writes as follows: "Two years ago I had a new studio built, and a few days back a square of glass was accidentally broken, and I noticed that the pieces had a decidedly yellow appearance, which the glass did not have when it was new. I have had another pane taken out, and that is just the same, as you will see by the enclosed pieces. Is it usual for glass to change like this? and does it not make the exposure longer when it does?"—It is by no means unusual for glass to change in colour by exposure to light, though rarely to such an extent as this has done in so short a time, that is, supposing it was colourless, or nearly so, when the studio was erected. Some kinds of glass do not change at all, or very little indeed. Of course when glass becomes of such a non-actinic colour as this has the exposure is, necessarily, somewhat prolonged.

E. A. C. will be much obliged by the Editors telling her, in "Answers to Correspondents," the cause of the mildewed-looking spots in the middle of the enclosed silver print. They showed themselves as soon as dry, but are the only ones out of a batch of fourteen prints. E. A. C. has noticed the spots before, among many also, sometimes larger and more marked.—**2.** Will the Editors kindly say what can be added to starch when used as a mountant to counteract any acid? E. A. C. has used it successfully for long, but one lot of prints mounted turned yellow as one sent. She has been told the starch must have been acid. Is this so? The starch is made with boiling water, but not allowed to boil.—**1.** The spots are due to sulphuration in the fixing bath. Either it is too weak or the prints have been allowed to stick together while in the solution. The latter is the most probable cause.—**2.** Good starch is scarcely likely to be acid. If it is it should not be used for mounting photographs. The Glenfield white starch may be relied upon. The partial yellowness of the mounted print is not caused by the mountant, but arises from the same cause as the spots in the unmounted one.

NORTH LONDON PHOTOGRAPHIC SOCIETY.—There will be an excursion to Winchmore Hill on the 9th instant. Train from Moorgate-street (Great Northern Railway), twenty-six minutes past two p.m. to Winchmore Hill Station.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, July 13, will be an *Entomorphising Apparatus in Case of a Break-down when Away from Home*. Saturday outing at Winchmore Hill. Train from Moorgate-street at twenty-six minutes past two.

In England, at a town called Deal, there is a pier, and when any amateur photographer ventures there with his camera he is compelled to pay two dollars and a half for the privilege of taking negatives, because the local photographers have represented to the authorities that amateurs were causing an injury to their trade. In the United States, at the head of Lake Michigan, a licence is now demanded by the authorities at the town of Mackinaw of fifty dollars.—*The Eye.*

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1419. Vol. XXXIV.—JULY 15, 1887.

THE BEST MODE OF BACKING PLATES.

WE return to the consideration of the practical treatment of this most important operation in modern photographic methods. Some of our readers, no doubt, will fail to see that the subject merits the importance we attach to it; but we unhesitatingly state that there are few negatives taken with unbacked plates that would not have been the better for the adoption of the method, and that there are some subjects which it would be absurd to attempt without this aid to accurate representation.

Let us first take into consideration our minor preliminary assertion. Who with practice in portraiture but has had an experience of the difficulty of taking a good negative where were violent contrasts of light and shade, or large masses of white in the subject depicted. A gentleman in evening dress, or even with a black coat and immaculate white cuffs, is a good example. Every one who has done much portrait work is familiar with the manner in which a beautiful grey fringe surrounds this white linen in lieu of an almost perfectly jet black; while as to a lady in a white dress, especially if posed against a white, or nearly white, background, it is a subject from which it is next to impossible under ordinary circumstances and with an average plate to obtain a negative free from "fog," this "fog" being simply a universally diffused haze from reflected light or lights. The whole cause of these disastrous results is explained in our last article. The light penetrates the film in a diffused form, and is reflected at the back of the glass of the plate; *i.e.* the place where two "different mediums"—glass and air—unite.

But these effects are as nothing compared with those obtained when the highest lights of the picture are brilliantly illuminated, while at the same time many large spaces receive but a dim light, yet need sufficient exposure to render them visible. Such cases, for example, as would be found in photographing interiors with windows on the farthest side, as in a church, for instance, or the glimpses of bright clouds between and about the spreading branches of a large tree. Any one who would attempt to obtain on an average dry plate a good negative free from halation from such subjects is certainly not a "past-master" in his craft.

We use the term "average dry plate" advisedly. There are dry plates and dry plates; some will give halation with almost every subject, though not invariably visible to the non-observant, while others will give a very fair negative, notwithstanding a stiff amount of contrast. But the two kinds of plate are easily distinguished without anylegerdemain. If any one have a thickly coated rich-looking plate, with a nice yellow-toned surface by reflected light, he will not have much to trouble him in this direction until the circumstances be-

come exceptional; if, on the contrary, he employ a plate with a thin translucent film, he must expect fog upon his delicate shadows and half tones, a lack of brilliancy in the general effect. A thin plate is not to a great extent the only cause of these defects, be it said; nor can it be asserted that there are no counterbalancing disadvantages when these evils are absent. We have no intention at this moment to discuss the advantages of thin plates; all our space, and much more, is needed for elucidating the particular subject we have selected.

When astronomical work is considered, the greatest difficulties of all are encountered, and we are strongly of opinion that it is very easy indeed to produce "coronal" effects from no other cause than reflection at the back of the plate.

M. Janssen soon became aware of this fact, and he used a backing of asphaltum to prevent the reflections. Long ago, the dry-plate maker, when collodio-albumen and its joys were fading into the distance to which it had been relegated by the superior claims of the then novel quick processes, daubed his plates alternately with anatto, lampblack, or burnt sienna rubbed up with water. Still later did Captain Abney show us the beauty of collodion containing dissolved aurine and roseine (*i.e.* magenta of a sort), and the beauties were not imaginary.

In the practical photography of everyday life, who would think of using a backing of black varnish to his plates? It would take a lifetime to remove it from a large batch of plates.

Then as to collodion. Let any one coat with tinted collodion the backs of a few dozen plates, with their occasional patches of emulsion wasted upon the wrong side, and then, after exposing, try to develop them in a rapid manner, and he will soon find the pecuniary cost and the practical nuisance in comparison with other methods. If he happen to be a sub-tenant holding rooms over shop premises we only venture to express the hope that he may not experience the pleasures of a lawsuit for damages to goods, owing to an overflow caused by the stoppage of his exit pipes, by pieces of collodion washed off the back of his plate during development.

If he trust to the old expedient of applying a paint made by the simple admixture with water of certain black or coloured pigments to the back of his plate, and there allowed to dry, his trustfulness will not by any means receive its full reward.

This is a statement easily verified. Let the experimenter paint a piece of plain glass with lampblack on one side only. He will observe it to exhibit a rich black by reflected light, the cause being that the index of refraction of water being—in comparison with that of air—so little removed from that of the glass itself, most of the rays incident upon it pass into this only slightly different medium, and are then absorbed by the black particles; and in that condition a dry plate so treated

would be in the best condition to exhibit freedom from halation with difficult subjects.

Let half an hour elapse, however, or, to expedite the examination of the effects from given causes, let the plate be warmed to facilitate the expulsion of the moisture. An extremely visible alteration will be observed: instead of the rich black (we are examining, it will be remembered, a plain sheet of glass to facilitate eye observation) we shall notice a cold bluish grey. The fact is, the water has evaporated, and over the larger proportion of the surface is replaced by a "different medium," air; so that reflection at the back at once reappears, modified only by the proportion (small, we may be sure) of particles which are so attached to the glass, that there is no film of air between them. For backing purposes this small proportionate area of what, for want of a better word, we may term optically cemented particles, is all that is available. What that proportion is may be guessed at by any one observing the reflected image, or rather images, of a very bright object. While the pigment paste is wet there is only one image to be seen; when the water is evaporated entirely there are two images visible; and we have to say that under no circumstances ought a backing to be accepted in practice which, after the lapse of, say, a day, allows two reflected images—one connected with the front and the other with the back surface—to be easily distinguished. How to avoid this duplicated image will form the topic of our concluding article on this subject, which to us appears of vital moment where high-class results are the object of attainment.

THE Convention of 1887 is now past, and takes its place in photographic history. Those who peruse the transactions of this body in the present and last week's issue of this JOURNAL will not fail to arrive at the conclusion that, with a greater amount of enjoyment in the form of excursions than it is the good fortune of most to condense into one week, there was also a greater amount of real solid business done than has ever been achieved during a similar period since photography was ushered into existence. That the Glasgow meeting will ever be equalled we can only hope, that it will be surpassed is extremely improbable. But the enterprising men of Birmingham, at which town the Convention of next year is to be held, will do all that in their power lies to ensure success.

92° FAHR. in the shade. This temperature was registered one day last week at Greenwich Observatory, and from 87° to 90° on several other days. When this temperature is reached, and is maintained for some time, a large amount of inconvenience and trouble is experienced by photographers. The "shade temperature," as registered out of doors, gives but a faint indication of that which prevails in the studio, where it has proved most trying alike to the sitter and the artist of life. In some studios—those of the old-fashioned glasshouse type—the heat, on some days, has been almost insupportable. Only those who have worked under existing conditions of temperature in the old collodion days, can fully appreciate the advantage and convenience of dry plates in hot weather. Now there is no longer the constant fear to distract the attention of the operator, that the plate will become dry before it can be exposed and developed, or the old dread of that old summer plague, "oyster-shell markings," to say nothing of the depressing and exhausting fumes of ether and alcohol in an ill-ventilated dark room. Imagine working wet collodion, for landscapes, this weather, in a small, stifling tent, with the collodion almost, if not quite, boiling as it was poured on the plate; yet it was done, and successfully, too. The modern photographer can form but a small conception of what the wet plate worker had to endure when working in an excessively elevated temperature.

Those who only use dry plates have very little idea of the difficulties which have to be encountered in their manufacture throughout

the hot summer months. During the past few weeks the consumption of ice in some of the larger establishments has, we are informed, amounted to several tons—indeed, of late, it has formed a no inconsiderable item in the cost of the plates. Those employing the Woodburytype, collotype, carbon, or any other process based upon gelatine, have also suffered the greatest inconvenience—a large proportion of the work having to be done in the night, or the very early hours of the morning. Fortunate are those who have access to a good supply of spring water just now. Although the temperature of the atmosphere may register 90° or more, it is rarely that spring water exceeds 52° or 54°. Vessels immersed in this, when freshly drawn, soon have their contents cooled down to a moderate temperature.

It is to be regretted that the manufacturers of cold air machines do not see their way clear to supply a smaller machine than they do at present. Such an apparatus, if it could be obtained, would find many useful applications in photography where ice is now employed. The smallest machine now in the market, costs, we are given to understand, about one hundred and twenty pounds, and has to be driven by a two horse-power engine. This size machine is far beyond the requirements of photographers, as it is capable of freezing several tons of meat and retaining it continuously in a frozen condition. If a smaller machine, which might be driven by a small gas engine, could be had for a moderate sum, few dry plate makers, we imagine, would be without one. Apart from the economy of a cold air machine, when once it is installed it possesses another advantage. When ice is used for cooling dry plates the moisture condenses on the top of the refrigerating chamber, and would drop on the plates unless special precautions were taken. But, with the machine, the degree of cold obtained is so intense that it is sufficient to convert the moisture into ice, which attaches itself to the walls of the cooling chamber. Some dry plate makers, we know, are using the larger machines simply because they could not procure smaller.

WHAT proportion of the silver consumed in sensitising the paper remains in the finished prints?—Various estimates have, from time to time, being given. Some have put it down as low as one per cent. only, while others have given it at five per cent., and higher. It is manifestly impossible to form any thing like a correct estimate to suit all cases, as so much must depend upon circumstances. For instance, if the paper be sensitised on a very strong bath, the amount of silver in the finished image will not be proportionately so large as if it had been sensitised on a very weak one. Again, the amount of chloride with which the paper is salted is an important factor in the case. So, also, is the negative from which the print is made. If that be a strong one, it goes without saying the chloride reduced in the printing will be far greater than if it be a very feeble negative. We refer to this matter here as some correspondents have recently made inquiries on the subject.

AN inquiry on a kindred topic to the above has just reached us. A correspondent wishes to know the relative proportions of silver and gold in the image of a paper photograph. This is quite as difficult a question to answer as that just referred to, because here again all must be dependent upon conditions. A print which has been deeply toned, of course, contains far more gold than if it were only lightly toned, and proportionately less silver. A few years back, Mr. William Bedford showed, at the Photographic Club, an ingot of gold which he had obtained from half a hundredweight of spoilt prints that had been toned and fixed. The ingot weighed one hundred and seventy-five grains. In addition to the gold, four hundred and thirty-five grains of silver were recovered. This showed that the image in Mr. Bedford's pictures consisted, as nearly as possible, of two and a half parts of silver to one of gold. It must be borne in mind that this gentleman always tones his pictures to a rich purple tint. If the prints had only been toned to a light reddish brown, then the proportion of gold would have been less and that of the silver greater.

ADVERSE criticism on the new coinage is almost universal, though it is chiefly confined to the effigy of the Queen. This is certainly disappointing as a likeness, which we were led to expect before the coins were issued, and, what is more, the portraits on the different

coins are not identical. They vary almost as much as those issued by the different illustrated papers. The effigy, be it a good or a bad likeness, should be the same on every coin. There is no reason why the dies should not be produced by photo-mechanical means, which would secure uniformity. From a negative a gelatine relief might be obtained and reproduced by electrotyping, then from the electrotype dies could be produced by pressure under the new system.

THE PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.

On Wednesday evening, as announced, the chair was taken by Professor Herschel.

After a few announcements relative to the further business proceedings and excursions of the Convention, Mr. J. J. Brinshaw delivered a brief lecture on the phenomena of polarised light, and the room having been previously darkened, a great number and variety of suitable subjects were projected on the screen by the lantern-polariscope.

The Chairman followed with some remarks complimentary to the lecturer, and spoke of the importance of photographers studying this, as yet, imperfectly understood branch of physics.

Thereafter a large collection of transparencies, including general scenes, views taken during the excursion the day previous and that same day by Mr. Armstrong and several others were shown on the screen—the whole being much appreciated by the audience.

We may here observe that although the lecture hall was large and closely seated, yet such was the number of those present that not only many were compelled to be content with standing-room as best they could find it, but several late comers had to take up a position outside the capacious door of the hall. Among the views were some of the "crack" yachts, including the famous "Thistle," for which the Clyde is so justly celebrated.

On Thursday evening, Mr. W. Lang, jun., presiding, the following business was effected:—

Mr. J. Traill Taylor exhibited and described three detective cameras, of which an account will be found elsewhere.

Mr. Jerome Harrison described the nature and uses of Pumphrey's films, and showed a film holder for using with them.

The following papers were read:—

PRETENDED PHOTOGRAPHY IN NATURAL COLOURS.

By W. E. DEBENHAM.

A SUBJECT which occurs to me as being one with which the Photographers' Convention may properly deal is that of processes for colouring photographs put forward as discoveries in photography. Every few years such pretensions have been advanced, commonly in connection with some old, abandoned, and repatented methods of applying paint; but recent occurrences demand, I think, that something more than passing notice should be taken of such pretensions, and the publicity which the proceedings of the Convention enjoy may, I think, properly be used to help to inform the public of the truth in the matter. Not only do photographers suffer in public esteem by their inability to produce nature-coloured photographs, which, by means of bold advertisements and untruthful paragraphs in some even of the leading newspapers, the public have been led to suppose are now accomplished by so-and-so's wonderful discovery; but when the time comes for these false pretensions to be exposed, the public, disgusted with having been taken in, is apt to regard photography itself as being associated with unworthy proceedings.

I was consulted some time since—probably from one to two years ago—by a gentleman who had had some connection with public companies, as to his taking an interest in a process which had been introduced to him as one of photography in natural colours. He sent me the specification, and when I next saw him I told him what the process was, and gave him my opinion that to bring it out as proposed would be grossly fraudulent. It did not occur to me that any one possessing any knowledge of photography would suppose that it had any value on its own merits, or that money could be made by it in any other way than by using it as an instrument of obtaining money by a false pretence. Independent of any want of novelty, the conditions of the process—backing up a transparency with a sheet of painted paper—appeared to me to hamper the artist to such an extent, from the difficulty of judging of the effect which his work on a plain tracing would produce when viewed through the transparency in optical contact with it, and from the difficulty in preventing stretching of the tracing and ensuring accuracy of register under the squeegee, that I considered that he would be hopelessly handicapped compared with those who painted photographs either in the usual way or behind the image, as in the

crystoleum and Lambert processes. Indeed, I should not be at all surprised to learn that the Cellierier Company have adopted the latter means—painting direct upon the back of the film—in place of that with which they started.

After the exposure in the photographic papers of the fictitious character of the Cellierier claim to the title—"Photography in Natural Colours"—their representative wrote that "the Board gave instructions to withdraw and discontinue any such heading to their processes (Cellierier and Parkes), as they do not wish to adopt any name of a possibly misleading or deceptive character." After this it is disappointing to any one who expected the Board to act up to this profession, to find that the title substituted for "Photography in Colours" is "Photographs in Colours," which is very much "such a title," and is certainly misleading. To my mind the only difference in the meaning of the expressions is, that one describes a process, and the other the pictures produced by that process; but both imply that the colours, equally with the drawing, are the work of nature, and not of the hand. On this point, however, as the question has been raised, I should like the opinion of the Convention whether it confirms that which I hold, and which I have found to be that of the public, or not.

Another process which has been recently announced as photography in colours is that of Mayall. In the *Globe* of May 17, in a paragraph headed, "New Discovery in Photography," it is said that Mr. Mayall "has discovered a means of photographing in colours." "The new camera does its work in colours almost instantaneously, and what rich and delicate colouring it produces!" Now it transpires that Mayall's is a hand-colouring process, and there certainly is no comparison between the credit due to the originator of any colouring process (assuming it to be original) and the honour to which such a discovery as that heralded in the *Globe* would have entitled its inventor. It is, therefore, to be regretted that in a letter of Mr. Mayall's which appeared in the *Globe* a few days later he did not distinctly disclaim the pretensions put forward in his behalf, but wrote in such a manner concerning wave lengths—quite irrelevant in a painting process—as would induce many non-scientific people to believe the claim to be genuine.

The writer in the *Globe* may have been misled by Mr. Mayall's heading: "My New Process for producing highly-finished Coloured Photographs without the aid of an Artist." A person who applies paint to a photograph is certainly a painter, even if a bad one; and with regard to colouring photographs, the words painter and artist are used and understood synonymously. If the words "without the aid of a painter" had been used in Mayall's heading there would have been a direct and obvious misstatement, which some might prefer, as bolder, to the suggestion implied by the words, "without the aid of an artist." Now, although "artist" is, as has been said, understood with regard to photographic colouring to be synonymous with "painter," and so it may be said that a photographic colourist must be an artist, even if a very bad one, whilst he exercises the art of colouring photographs; yet he may do them so slightly or so badly that it may be argued that in one sense he cannot be called an artist. I have not seen Mr. Mayall's coloured productions, but I understand that a gentleman attending your Convention—Mr. J. Traill Taylor—has an example which is to be shown, and you may be able to judge whether the colourist is entitled, in the sense of ability, to be considered an artist or not.

What is to be said of the conduct of some of the leading newspapers in such matters? If a patch of granite without a grain of noble metal in it is to be offered to the public as a rich auriferous deposit, the papers will not so far lend themselves to the transaction as to call it a great discovery, and speak on their own authority of the purity and abundance of the gold there found. Why should they be so much less scrupulous when photographic matters are in question? Whether there is the smallest justification for the praises that have been lavished upon the beauty of the results of any particular colouring process may be judged by those who have seen them. There certainly is none for statements that the colours are the work of nature; and it cannot be supposed that writers who do not scruple to make such statements will hesitate to add flattering descriptions as to beauty, especially as the last-named quality may, after all, be said to exist only in opinion; and a writer might even maintain that he considered that to be beautiful which in the eyes of most people would be considered vulgar, trashy, dingy, false, or gaudy. Are the untrue statements that have appeared due to false information derived from those likely to profit by them, or are they due to the incapacity or venality of the writers? This is a question which it appears to me the proprietors of the newspapers in which such puffs have appeared should, for their own honour and interest, investigate, and to which they should give some sort of reply, at the same time that they insert a withdrawal of the puffs as publicly as they have made them.

It is certainly possible for a journal to guard itself against being made the instrument for propagating untruthful puffs in scientific or pseudo-scientific matters. This is proved by the fact that they cannot, so far as my observation goes, be got into the *Standard*. I don't suppose that this journal is quite alone amongst leading newspapers in being clean-handed in this respect. Perhaps it is in the knowledge of some of the members of the Convention which leading papers have, and which have not, lent themselves to the misstatements referred to. If the present discussion should induce some of the offending or misled journals to

make the *amenité* suggested, and cause them to be more careful in the future, it will not have been in vain.

METRICAL MEASUREMENTS.

By THOMAS BEDDING.

I VENTURE to hope that if at this Convention, which at the moment of writing bids fair to be attended by a preponderance of, I will not say professional, but business photographers, some little time is devoted to the consideration of a purely commercial matter, in which our non-practising brethren are as intimately concerned as ourselves, the departure will not be without its advantages, however slight. Harking back for precedents and inspiration to the literature of the Derby meeting, one feels a strong inclination to follow the beaten track instead of prospecting round on one's own account, and it is only the danger of clashing with somebody else that has weighed with me in the choice of so comparatively an out-of-the-way subject. But for these scruples, the exquisite variety of the *debutant* would infallibly have lured me into the fascinating mazes of orthochromatism, or photography in colours, or the recent and continuous opposition to the employment of ammonia in the developer. As it is, I must dissemble, and leave to some one like the President the congenial task of pulverising the natural-colourists, the potentialities of orthochromatism to Mr. Wellington or Mr. Edwards, and the philosophy of development to its own particular guardian angel, Mr. Pringle. As you will have inferred from the title of the paper, I intend going into figures.

Now from figures, on the authority of the right honourable gentleman the Member for Midlothian, you can get very respectable poetry, not perhaps as musical as Robbie's or as sonorous as Scott's, but still something rhythmical, if only blank verse. I shall not test the truth of this; I only refer to it in order to quiet those of you who are inclined to be disagreeable because my subject threatens to be so dry. Most of you have, at some time or another, "done" a British Association week, and you must have noticed how sparsely attended has been, for example, the section in which Professor Cayley affably discoursed pure mathematics, and how crowded that where Sir John Lubbock airily prattled about ants and other interesting little people. I hope I shall not be treated like poor Professor Cayley, for if you will wait to the end, you will find that although I may not have quite realised Mr. Gladstone's enthusiastic belief, you will at least have had plenty of feet and metres, which, as you know, are the very framework of all poetry.

To come to the point: I advocate the adoption of the millimetre instead of the inch or its fraction as the unit of all photographic measurements. Of course it sounds revolutionary, this sweeping condemnation of the dear old linear inch, which probably arrived with Julius Caesar, and equally, of course, the cultivation of the millimetre in its stead must be a dream; but, gentlemen, all changes are revolutionary, and dreams are the motive-power of progress. The metrical system of measurements is commonly called French, thus leading the unthinking to suppose that it only flourishes in the land of its origin. Nothing of the sort. In every capital from Madrid to Constantinople, from Christiania to Rome, photographic apparatus and plates are made to metrical scale. The system, in fact, is European. The United Kingdom alone holds aloof from it, and adheres to the antediluvian inch, just as it adheres to its own indefensible currency and many other anachronisms that make people of a progressive turn of mind very angry with her. But we shall have to come to the millimetre some time, just as by stress of circumstances we shall be compelled to reform our coinage. Manufacturers are the chief sufferers by the present state of things. For example, the maker of dry plates, following the standard scale of sizes, gets his glass cut to inches, halves, and quarters, and, when ordered, to eighths and sixteenths. He quotes for the chief foreign sizes in his price list, but he only supplies them upon indent, for he has not the courage to stock them. It is different with the French, Belgians, and Germans, some of whom, as you may see from the advertisements, make and stock all their goods in English sizes. Somebody may possibly whisper, "What about Continental tariffs?" I reply that the superiority of most British goods over foreign ones is so great that if they were made and stocked in Continental sizes, and systematically pushed, nothing but cent. per cent. *ad valorem* duties would shut them out. Even now, under the present slovenly régime, the European sale of some of our products is great, but it might be a hundred times greater. Foreign dealers and photographers desirous of trying our specialities in metrical sizes find that they must wait days, weeks, until they are made—a diversion of which they soon tire. Consequently they patronise native products at a gain of time and a slight loss of quality. Again, suppose a photographer at home wishes to try foreign papers or plates which do not happen to be made in English sizes; his slides and frames will not take them unless adapters and carriers are made, which means a loss of time. From these two illustrations you will see that in consequence of the tenacity with which we cling to the old order of things, commerce and the individual are at an appreciable disadvantage compared with the rest of Europe.

The permanent change from inches to millimetres would involve no trouble at all to makers of glass, cameras, papers, cards, ebonite, porcelain, frames, &c. Some of them, of course, work to the latter scale at

present, but, as I have shown, only intermittently; it is a pity they won't keep to the small unit altogether, for then we should get more accurate measurements than we do now. In regard to dry plates, the two sizes in most common use among us are $4\frac{1}{2} \times 3\frac{1}{4}$, or *carte-de-visite*, and $6\frac{1}{2} \times 4\frac{3}{4}$, or cabinet. On the Continent the two sizes most widely used are 90 mm. \times 120 mm., and 130 mm. \times 180 mm., which, when reduced to inch measure, are respectively $4\frac{3}{8} \times 3\frac{1}{8}$ and $7 \times 5\frac{1}{8}$, about; in each case a trifle larger than our quarter and half plates. It would be a simple matter, assuming that we cut our plates by metrical scale, to increase the area of the *cartes-de-visite* and cabinets to these sizes ($4\frac{3}{8} \times 3\frac{1}{8}$ and $7 \times 5\frac{1}{8}$)—and, in fact, the same in regard to all the others, of which the 100 \times 130, the 120 \times 160, the 180 \times 240, the 210 \times 270, the 240 \times 300, the 300 \times 400, respectively approximate to our 5 \times 4, double quarters, 9 \times 7, 10 \times 8, 12 \times 10, and 15 \times 12. Then our foreign clients could have their requirements supplied at a moment's notice, the photographer at home could try and test Continental novelties as easily as he does English ones, and the innocent abroad in want of a dozen plates could drop into the Turkish or Spanish dealer's for them untroubled by any misgivings as to whether English sizes were kept or not. The loss to international trade through our obstinacy must be vast; the inconvenience to professionals and non-professionals alike enormous. The millimetre would remedy all that. I have an idea that a reformed currency would help bring about a change. America has a decimal coinage; let her go a step further and take the metrical system under her wing, and she will be able to swamp the European markets with photographic goods as easily as patent medicines. Some of us, happily, employ the metrical system habitually—gunmakers, to wit, for barrel bores; accuracy in photographic measurements is just as important. A badly cut plate is a common curse, so is an ill-fitting slide; both faults, I believe, may be traced to over-generous marginal allowances.

In suggesting the substitution of the millimetre for the inch and its fraction, I am in effect advocating a total reformation of present sizes; but this sounds more iconoclastic than it really is. Take a metre measure, place it alongside a two-foot rule, and compare the ten or twelve principal Continental sizes with their near equivalents in inches, and you will see that it merely means in some cases a slight increase, in others a small decrease, in our own sizes. The whole matter is innocent of difficulty, and everybody would benefit by the change. The inch is an inehular—I mean insular—prejudice. Some day, when Sir Edward Watkin has tacked Dover on to Calais, and a tunnel connects Scotland with the Emerald Isle, we shall become to all intents and purposes a bit of Europe; then the metrical system will be forced upon us. We are much in the position of the late Mr. Mahomet; other nations won't adopt our system, so we must adopt theirs if we wish to be in a line with them. By cutting our glass and papers and woodwork to millimetrical scale, we shall have adopted the only philosophical and international system of measurement extant; ensure exactitude, which we rarely get now; save time and make money; and facilitate a better intercourse between antagonistic peoples who, as things look at this moment, are too fond of snarling and quarrelling over much smaller things than even a millimetre. Who knows but that the conversion of this country generally to the metrical system may not be the means of smoothing away the too easily provoked susceptibilities of the Gaul, the Russ, and the Tenton, and of promoting lasting concord between ourselves and our neighbours? I make the Peace Society a Jubilee present of the idea.

I have designedly treated my subject in as light a vein as possible for two reasons: first, because it is possible that the majority of my listeners may be too tired to appreciate a strictly academic treatise; second, because there is no earthly reason why even the heaviest and most dry-as-dust topic should not be approached in an amiable frame of mind.

ELEMENTARY PHOTO-MICROGRAPHY.

By ANDREW PRINGLE.

CIRCUMSTANCES over which I have unfortunately no control cause me to prefix to my title the qualifying adjective "elementary." It may appear to many present that in addressing a meeting on this subject at all I lay myself open to the charge of presumption, for I cannot deny the "soft impeachment" that I am in photo-micrography myself only a tyro, and, in colloquial phrase, a "duffer." But, gentlemen, I have often noticed, and frequently stated, that more is to be learned from the failures of a careful worker than from the brilliant successes of a natural genius, and it seems certain that a man fresh from the difficulties attending any pursuit is more likely to remember the existence, the causes of, and the cure for these troubles than the man who left them behind years ago, just as it is probable that our sons who left school last year are more conversant with the eccentricities and atrocities of the Greek particle than we are who have for years directed more immediate attention to the eccentricities of the share market, and the atrocities of the butcher and the tax-collector. Anyhow, the very briefness of my experience in photo-micrography must serve as my excuse for addressing you on a matter which may be child's play to many of you.

Of the utility of photo-micrography there can be little question, and its utility is not by any means confined to the province of the great achievements of "past masters" in the art. I doubt even if the sphere of greatest utility is to be found in the use of the very highest powers

upon the minutest and most recondite objects. Moreover, however great the experience and talent of the microscopist, his purse must be as long as his practice and as deep as his knowledge if he means to travel into the highest realms of the science whose borders I mean to touch. Be this as it may, I have no present intention of travelling beyond the country I know—that it is to say, the very first and simplest operations for the production of photo-micrographs.

I will begin by pointing out the subjects that suggest themselves to my mind as presenting only slight difficulties, and yet fraught with vast importance to humanity. I do not think I need point out to a body of photographers—nor, indeed, to any body of reasoning beings—the superiority of a photographic delineation of any object whose qualities depend on its reality rather than on its ideality to any delineation that can be made by hand, however deft, guided by eye, however acute. Even the most perfect transcript that could be made with the aid of a camera lucida must fall immensely short of a transcript by the unerring and invariable action of light. The finest line that ever was drawn by mortal man is a cable in comparison to the lines that may be produced by photography. Now, the very essence of micrographic delineation is clearness and detail, and I submit to you that for clearness and fineness of detail the photographic print must leave far behind all manual dexterity.

What, then, are the objects to which photo-micrography lends itself with the most conspicuous excellence? Undoubtedly such objects as depend for our knowledge of them on their histology, on their most minute markings, on their varying appearances under various kinds and directions of illumination—as, for example, under reflected, transmitted, direct, oblique, and polarised lights. To scientists studying minute organisms, or minute portions of organisms, the greatest difficulty and yet the most essential point is to examine and get delineations of these objects under varying conditions of lighting, and so to become acquainted with the objects that one object can never be mistaken for another, nor one condition for another. In the first place I will mention physiological and pathological objects—in other words, portions of animal tissue in a normal state, and in a state of disease or abnormality. From experience I can state that many objects of this kind are not difficult to photograph in such a manner that the delineations become of great interest and value for those benefactors of our race—physicians and surgeons. Again, there are many of the lower living organisms whose nature and habits are obscure, though their dimensions are not very minute. There are also vast tribes of diatoms and foraminifera whose nature is as interesting as their appearance is beautiful. The geological formations of our earth form a branch of science of the last importance to man, and the study of them with light direct or polarised is one of never-ending interest and variety. The substances which afford nutrition to our bodies and act as counter-agents to the waste going on constantly in our life, are, for the most part, amenable to microscopic examination, and, what is more to my purpose, to photographic delineation. Lastly, the germs of disease, not only in the animal but in the lifeless organisms so familiar to us, can be, and have been, and shall be, if we are spared, examined, distinguished, and portrayed by microscopic and photographic agency, till their natures, their habits, their transmission, their reproduction, their annihilation, if it please Providence, shall be matters not of mystery confined to the *salvans*, but understood by all the people. This, gentlemen, is a noble ambition, and the path to its fulfilment is not a dreary, nor a dark, nor a criminal one; the path is illuminated along its course by gleams of highest interest, by intense satisfaction, by a knowledge that the pursuit is glorious and the end philanthropic. The higher flights of photo-micrographic science are surely arduous, beset with enormous difficulties, but we must remember that, as we progress, the difficulties vanish behind us, and what we now look upon as well-nigh impossible, will, in the future, appear pigmy impediments. The very simple operations I propose to mention to this meeting appeared, not so many years ago, to the mass of photographers, as matter of the greatest uncertainty and difficulty, and only to be fully understood and successfully worked by men who have spent much time in mastering the details of microscopic science.

Having now, at perhaps superfluous length, delivered a sort of apology for photo-micrography, I will proceed to practical matters.

The first thing to decide is what kind of objects we mean to tackle, or more particularly, what extent of amplification we mean to attain. My earnest advice is to “*ea’ canny*”—*Anglice*, “drive slowly”—at first. Certain failure will follow temerity in this respect. The object for a first trial must be thin, lightly if at all stained; be neither too opaque nor too nearly colourless. The objective should not be a higher power than one inch, while a two or three-inch glass would be preferable. The microscope eye-piece must not be used, as it entails certain difficulties, and in some cases absolute failure.

A word or two about the objective, which is, perhaps, the most important part of the whole apparatus. Microscopic objectives made for ocular examination of objects sometimes have their visual and chemical foci not in exact correspondence; a lens of this uncorrected kind is useless for photography. The fault may be remedied in several ways, but my advice is to get a properly corrected lens at first. It may have been De’il’s luck attending me, but it so happened that the two-inch, the one-inch, and the quarter-inch with which I started were all faultless in this respect.

As to the light used. I prefer for simple work a paraffine lamp to other radiants. My start was made with a small cheap lamp of this kind, such as is usually sold with moderate-priced microscopes; my lamp had only a wick of about a quarter of an inch wide, but I recommend a wider wick, say one inch, and that used with its edge turned nearly straight towards the object. A multiplicity of wicks I consider a downright disadvantage; the smaller the area of radiance, commensurate with brightness, the better. I believe an arc electric light to be the best of all, but it is not needed for any such simple work as I am treating of now. An achromatic substage condenser is another valuable aid for advanced work, but for our present purpose an ordinary bull’s-eye, called a “stand condenser,” is sufficient. This is placed near the light with its flatter side towards the light.

My own first arrangement of camera, tube, object glass, and stage was very convenient for work with low powers, where searching for the object was a matter of ease. I will describe it in a few words and then pass it, for I found it rather expensive, somewhat awkward at times, useless for really higher-power work, and excelled for any work by an arrangement which I shall afterwards explain, and one that finds favour with the best workers both for easy and difficult work. In my arrangement the microscope tube, with coarse and fine focussing arrangements, screwed into a cone fitted to the camera front, while the stage, with object clips and a rotating diaphragm with apertures, were fixed to the end of the tube by a bayonet joint. By this arrangement the diaphragm, object, objective, and tube were all axially centered on the ground-glass centre. But there was no fixed arrangement for centering and keeping central the light and the condensers, and from that fact arose all my first troubles. In our work one of the first necessities is absolute centralisation of the whole of the apparatus: without this no good can be done. It seems to be impossible to fix all the necessary parts centrally together without involving great difficulty in the operation of finding the object, and the best plan appears to be to divide the entire apparatus into two parts, the components of each part being fixed centrally, and then by means of a “stop” to ensure centralisation of the whole on the longitudinal axis when the two larger divisions are brought together and aligned by means of the stop. The best arrangement I have seen, and it is approved by good authorities, is one whereby the microscope tube, stage, object, condenser, and light are all centered on one baseboard, while the camera runs axially centered along a short slot on a second base. The microscope base is pivoted on a centre, so as to swing laterally, for a purpose which will soon be explained. The object is first staged and found with the microscope in the usual way, the condenser and light centered on the base, carrying microscope, stage, condenser, and light, and then the base carrying all these is swung round to the longitudinal axis of the camera, being arrested there by the fixed stop aforesaid. The camera is now pushed forward along the slot aforesaid, so that the end of the microscope tube projects into the camera and a light-tight junction is formed by means of black velvet or accurate fitting of the parts.

I know quite well that few of you will understand this very miserable description, and I have no means of offering you a drawing, but I propose to ask our good friends the *pressgang* to publish a drawing of the apparatus as made by a well-known London firm, Messrs. James Swift & Son. I believe the design is due to a considerable extent to Dr. Crookshank, who read at the Photographic Society in June last a paper on *The Photography of Bacteria*; to describe that paper as “interesting” would be to “damn it with faint praise.” Dr. Crookshank may consider himself responsible for an attack of temporary insanity, if not permanent bankruptcy, on my part.

We must now devote a moment to the camera. It should be a good strong camera, with a stretch as long as possible, for on the amount of stretch depends, *ceteris paribus*, the amount of amplification. No swings-back of any kind are required; they are, in fact, better absent. The commonest make of wooden camera will answer, provided it will stretch and is strong and light tight. For simple work and small amplification the ground-glass of the camera usually suffices for focussing, but where very fine work is to be done with high powers the ground-glass is too coarse. I have used two surfaces for focussing in such cases, in each case placing the prepared plate in a wet-plate slide, drawing the shutter, removing the back, and focussing on the plate with its prepared side to the front. The first way of preparing a plate for this purpose is to rule a few lines—not scratches—with a diamond in squares on the face of the plate. This gives the very finest surface for very high powers and difficult subjects. A plate intermediate between this and ground-glass is prepared by just fogging a sensitive gelatine plate, developing and fixing it, bleaching if necessary with mercuric chloride. This plan I found in a book—the author’s name, I am sorry to say, I forget; it is a capital dodge. In all cases a focussing eye-piece will be required. I use the ordinary focussing ocular used in photography, but I am careful to have it itself carefully focussed by examination of a small speck on a window pane.

I think we are now in a position to suppose ourselves about to make a trial. It is well to arrange for a week’s absence from the family circle, pay the household accounts, lay in a good supply of cooling drinks and a few pounds of tobacco, pay an affectionate farewell to the babies and a ditto embrace to the missus; for the new-born photo-micrographer is not much good to anybody till he has cut his first tooth. There is an

irresistible and engrossing fascination in this work that cannot be escaped nor ever forgotten. When I began I did not for three weeks get beyond a distance of about fifty yards from my dark room. I was smitten as with a pestilence; a grim mania for new objects to conquer possessed me; I revelled in the very names of tubercles, Graafian vesicles, malignant tumours, sloughing phagedawa, tapeworms, bugs, fleas, lice, and nauseating skin diseases. The horse parasite was of more importance to me than the horse in the stable. My flowers suggested to me only the names of red spiders and aphides. Paring my nails became a polariscopic operation. I would have stewed a mouse for a single hair, stormed a bee-hive to get a sting, and I even exoriated myself for a specimen of *tinea versicolor*.

This, however, is not business, though it is truth. Nothing but common-sense and experience can teach us to centre our object on the ground-glass and to focus it. The apparatus I have described ought to explain itself. It is necessary to know in the first place what points of our object we require to bring out particularly. I made several photographs of various objects before I discovered what were the parts that I ought to emphasise. In many cases I had actually to ask what the important part was. If we try to photograph complete objects on anything like a larger scale of amplification, we shall find optical difficulties almost insurmountable at the very outset. Our lens will want "penetration" or "flatness of field," and practice alone will teach us what our lenses will do and what they will not. "Penetration" is the equivalent of what we call "depth of focus;" "flatness of field" corresponds to same extent with our "covering power." The best plan is to begin with some very thin flat object of considerable area and fairly light colour, and to find out to what extent we can enlarge it with a rather low-power lens. We must find out once for all, to save trouble, the amount of our various amplifications. Here is the way to do this. Put a stage micrometer on the stage. The lines are drawn at distances of one-hundredth and one-thousandth of an inch apart on the micrometer. Focus the micrometer lines at the distance we intend to work at and with the lens we intend to use. Then measure the interval from one line to another on the ground-glass, and a simple calculation will tell us our amplification. If on the ground-glass the one-hundredth lines are exactly one inch apart, evidently the amplification is $\times 100$, if quarter of an inch the amplification is $\times 25$, if three inches it is $\times 300$. I made measurements with all my lenses at all my distances, and wrote a list of the results, so that now at a glance I know the extent of my multiplications.

I soon found that sometimes, though I got my objects fairly well represented in my prints, I got poor grey backgrounds. I therefore proceeded to find out by experiment the exposures necessary to give black negative backgrounds when no object was on the stage. These results, too, I tabulated, and they now form a list of minimum exposures for the various lenses and distances. I found the whiter the light the better the background, so I recommend the addition of camphor to the paraffine in the lamp. I hope soon to discard paraffine entirely in favour of the oxy-hydrogen light.

So far as I have found out by perusal of books on photo-micrography, the writers for the most part have been very good microscopists but rather shaky on photography, and so far as I have seen the producers of photo-micrographs of magnificent microscopic qualities have not been fully alive to the necessities of a photo-micrographic negative. What we want is not what we call in photography a good negative. We want for photo-micrographic work a negative that in pure photography would be called "flat." In short, we should sacrifice everything for sharp and full detail. Density in parts is no doubt very pretty, and very artistic, and very agreeable to our notions, but it is out of place in a photo-micrograph. A photo-micrograph is a purely scientific production, there is no fine-art about it, however much people may quibble on the matter; and we must put aside all ideas of balance, symmetry, pictorial composition, and chiaroscuro. What we want is material, not ideal. I spoiled a good many negatives by trying to make pretty pictures and good negatives according to usual acceptance. I am very fond of *Pictorial Effect in Photography* both to read and to practise, but we must ignore Mr. Robinson—forget him we can't—in photo-micrography.

There are two classes of objects which we may have to photograph. Class I., Dense, semi-opaque, highly coloured. These sometimes cannot be photographed really well at all, but the line to follow is to use a rapid plate, ample exposure, and perhaps a tinted light of, say, blue colour. These should be highly developed with small percentage of pyro. Class II., Colourless or very thin but not transparent objects. (There are many objects so clear that they cannot be photographed by direct light at all. I hope to say more of these next year.) For translucent, or thin, lightly coloured objects, we require a white light, shortish exposure, and a slow plate giving contrast, which we may enhance by prolonged development.

Gentlemen, I have succeeded, as you will admit, in speaking a very great deal and saying very little indeed. I think I never saw an effort so successful in this line as my Convention paper. But I assure you I have not over-guessed wilfully; my mind was so full of my subject that, like a London street on a big day, my utterance got blocked. Next year, D.V. and W.P., I hope to address you on this subject in terms no less enthusiastic, but much more specific and useful.

GELATINE EMULSION.

By A. L. HENDERSON.

WHEN I had the honour of reading a short paper at the Convention last year I mentioned the fact, that by the addition of a small quantity of nitrates and bromides to a finished emulsion much greater rapidity and density could be obtained, and that doubtless further experiments would reveal or explain many things that at present are still inexplicable. I promised that I would at some future occasion detail other experiments. I will now endeavour to redeem this promise.

I think I have stated that if an emulsion is set and remelted several times greater speed and a finer quality is the result. My explanation is this, that by the contraction of the gelatine and the subsequent remelting the bromide of silver is broken up and altered in crystalline form. Now I know that it will be argued that, if emulsion is kept at a liquid temperature the same result would follow. I have tried the experiment of keeping half of a batch at about eighty per cent. for ten hours. Setting and remelting the other half four times during the ten hours there was a much greater increase of speed and density in the latter half. Another year's work with the separator corroborates all my previous statements concerning the value of the machine in emulsion making. The full value of the ripening action by the addition of nitrates, &c., to the finished emulsion, can only be gained by a complete elimination of the emulsifying gelatine and biproducts. I do not say that the ripening action will not take place in a washed emulsion, but there is an uncertainty about it. The separator has shown me, that so long as the temperature of emulsion is kept down there need be no danger of fog, especially in the presence of caustics; yet, with a large quantity of carbonate of ammonia, an emulsion may be boiled for a considerable time without any fog appearing.

One of my latest dodges is to make an emulsion with carbonate of ammonia separate, add fresh gelatine, nit. potass, and bromide, and then, to prevent decomposition of the gelatine, by addition of a small quantity of chrome alum. I keep this emulsion liquid at a temperature of 98° to 110° for twenty-four hours; this increases the speed from, say, 16 to 22 on Warnerke's sensitometer. A further prolongation of heat will generally require a fresh addition of chrome alum, when a still higher reading will be obtained; and, what seems very strange, the camera reading will be much higher than the sensitometer one. I have had two emulsions, both giving 16 Warnerke with a rapid shutter; and using a stop $\frac{1}{37}$, I had a fully exposed negative in the one case and the other only a faint indication of an exposure. There is a remarkable ripening action by the addition of fresh gelatine, bromide, nitrate, and alum. The method of breaking up of the bromide of silver was first published by Professor Stebbing, and at the time I tried it I found that the effect was obtainable without the bromide, yet I failed to see any advantage. I will now, as an experiment, show you, that by mixing nitrate of silver and bromide of potassium in water, then washing the precipitates and adding a few grains of gelatine and applying heat, that a remarkable breaking up of the bromide of silver goes on. Of course, as the salts are so perfectly removed an oxidation or alteration of the bromide is likely to take place when heat is applied: the addition of the nitrates, &c., as aforesaid, tends to prevent this. Some of the gentlemen here may not have seen the action of the centrifugal separator. Messrs. Watson, Laidlaw, & Co. have kindly placed one of their newest forms of machine at my service, with which I will give you a demonstration.

HOME PORTRAITURE.

By T. N. ARMSTRONG.

WHEN requested to prepare and read a paper on Home Portraiture, I had considerable doubts as to the desirability of selecting such a subject. At first it occurred to me such could have but little, if any, interest to the majority of our professional brethren. On the other hand, seeing we were to have among us so many amateurs to whom a few practical remarks on what I consider the best means of taking portraits in an ordinary room might be of interest, I deferred to the wishes of those entrusted with our arrangements, and have put together a few remarks which I trust will be acceptable.

It seems to me by far the larger proportion of amateurs give but little attention to home portraiture, nor is it difficult to find the reason, for of this a very general opinion exists that without the aid of a studio, with its special advantages for lighting, &c., an amateur cannot hope to produce results that will in any way compare with professional work. Now I am not one of those who think thus. On the contrary, I maintain and hope to be able to show you that there is no reason why an amateur in many instances should not be able to produce really first-rate specimens of portraiture without the aid of a studio.

At the outset, let me say I consider the proper lighting of the sitter of paramount importance, and here it is an amateur who for the first time attempts to take a portrait in an ordinary room is likely to err. In his eagerness to get as much light as possible, the blinds will be run up, the windows scrupulously cleaned, and everything done to flood the sitter with all available light. This using of too much light is one of the first errors a beginner is sure to fall into. If, for instance, we place a sitter near an ordinary window having a good open view, and expose a plate,

on developing same it will be found that the contrast from light to shade is too great; the side next the window will be found too light, the off side too dark. What is the reason of this? A beginner will very likely imagine and say, "Oh, it's no use trying, I have not enough light." Now, in reality, such is not the case; it is not that there is an insufficiency of light, but that it is not of the proper quality, or, in other words, is not sufficiently diffused.

Now, seeing that diffused light plays such an important part in portraiture, let us briefly consider what is meant by diffused light, and then how best to obtain it.

There are two kinds of diffused light, namely, artificial and natural. The atmosphere being filled with floating particles, all of which being more or less opaque are continually reflecting and absorbing light, those particles that are transparent are constantly refracting and absorbing light, and this constant changing of the course of the rays until they are thrown into every conceivable direction is called natural diffusion. You will readily perceive we have no power of controlling such. But it is not so with artificial diffusion; in portraiture it is a most important factor, and we must bring it to our aid to soften high lights, and break up too strong shadows. But how are we to obtain it? When any translucent screen is made to intercept the direct rays of light, and the atoms of which the screen is composed reflect or refract the rays so that those which come through have lost their general direction, some passing one way, some another, are said to be diffused. This we call artificial diffusion. To obtain such, procure a very thin muslin screen, which place between the window and the sitter, out of range of the lens, in such a manner that all the rays which fall on the face must pass through the gauze. This done, if we expose another plate on our sitter, we will find a very material change has taken place. Not only has the high lights, which were too hard previously, been softened down, so to speak, but the dark side of the face will appear to have been lighted up, thus reducing the violent contrast which previously existed.

Having briefly referred to the necessity of breaking up a too concentrated light, now let us consider the best means of employing a translucent screen so as to throw the light from a proper angle on our sitter.

In making choice of a room for the purpose of taking portraits, choose the one with the tallest windows you can get; the higher the window the better it will enable you to get more top light. If you succeed in getting a room with a high window, begin by blocking out with a brown curtain three feet of the light at the bottom. This is easily done with an ordinary muslin blind run on a stick, and which can be dyed by steeping it in a decoction of coffee. Then, with another very thin white gauze blind, screen off the light to the middle of the window, and then bring into operation your thin white gauze screen, which rests on the top of the bottom sash, slanting inwards at an angle of about forty-five degrees. Now place your sitter as low as possible, and content yourself with taking a head and bust on a light background. This done, you will not only have your light of the proper quality but from the best direction; your high lights will not be too hard, nor your shadows too deep. Bear in mind, however, when lighting your sitter, that the shaded side of the face is often very deceptive; the shadows must appear lighter to the eye when posing than they will be in the resulting print. To enable you to light up the shaded side of the face I know of no better or simpler reflector than the homely clothes-horse, over which is thrown a white sheet. In using a reflector, do not throw the light from behind the cheek, but rather throw the light on the front of the shaded side, allowing the back part of the head to be in the deepest shade.

Let some of you may imagine that this screening of the light will require unduly long exposure, let me here say that, working with an ordinary cabinet portrait lens, my exposures rarely exceed six seconds when using a rapid dry plate. But some of you may say, What about facilities for various styles of lighting? In this we are not even tied down. I have brought with me to-night for your inspection a few examples of my home work, and if you examine them you will find several different styles of lighting. It is wonderful what a variety can be obtained with a little practice, working on the lines I have laid down.

I have spoken first of lighting because, in my opinion, it is the most important of all the many manipulations required in portraiture. Get as much light as you can, but be sure it is of the proper quality; then a little practice will teach the intelligent beginner. It is wonderful how soon he will find out how best to place and light his sitters, so as to obtain proper gradations of high lights, middle tints, and deep shadows. Your chemicals will never give you these if your lighting is wrong; and, beyond everything, do not fall into a practice of under exposing. Great care must be observed in this. The great point and beauty in portraiture is softness; it is got by properly lighting and fully exposing, and in no other way.

Next in importance to lighting comes posing and expression, and here the amateur is not handicapped, but in reality has advantages which his professional brother has not. One advantage which he has, and which is of great importance, is an intimate acquaintance with his sitters; he will most likely know his or her little soft points beforehand, and what little chord to touch and preparation to make so as to put them in the best of humours. I have seen a cup of tea handed to a lady just before sitting work wonders in the way of making her comfortable. Be ever on the watch for even such a trifle as this, and never lose an opportunity of getting your sitter in a natural vein. In posing, the amateur must

study, however, and, above all, do not weary your sitter with manning them about first one way then another. Very likely the first position they will take when sitting down will have something natural about it. Watch for such like a hawk, and if you see they are not going to fall into a natural position, wean them off by drawing their attention to some little triviality, such as letting them walk about a bit, or looking at something pleasing or comical. You are, or should not be tied down for time like many a professional; the proper time to be quick is when you have got a good pose and expression. Then be as quick as a needle in a machine if you like. Expression is of the first importance in portraiture. The best hints I ever obtained on posing and expression I derived from what E. K. Hough wrote, and on this head I cannot do better than quote his own words.

He says:—"We will suppose the sitter to be the centre of a circle with diverging lines, like the hub of a wheel with its radiating spokes; suppose this wheel twenty feet in diameter, and the spokes one foot apart at the periphery. The junction of these spokes with the rim we will call points, like a compass. Now let us place the sitter at the hub, looking straight before him, body, face, and eyes, to the camera, ten feet away, at the outer edge of the circle; this we may call a position of neutrality—impassive, inactive. Now, the body remaining in front, the head and eyes turning to the left or right, if ever so little, there begins to be expressed activity, thought, emotion, in which the eyes play an important part, and a part that may be largely brought under control, else there were no use describing it. To illustrate—If the head be turned two points away from the camera, the body remaining front, the eyes to express an easy, animated, but not deeply interested, attention, should be turned nearly to the third point. When the head turns from the body to the fourth point, the eyes to correspond should turn nearly to the sixth, thus expressing the same kind of easy, natural interest, but more active and more interested; and this corresponding divergence amounts nearly to a definite ratio whether the turning be more or less, being as two to one. Two of the head from the body to one of the eyes from the face, or, in other words, in turning the eyes to an easy point, right or left, the head must naturally turn about two-thirds the distance. This ratio of divergence we will call normal, and we shall find it giving about the kind of expression generally preferred in portraiture. Moreover, we shall see that any deviation from this normal relation immediately begins to express something different, often something not at all desired. For instance, the body remaining front, with the face and eyes both turned full upon the third or sixth point, or any intermediate point, there would immediately begin to appear an absorbed, deeply interested gaze expressing anxiety, surprise, or other emotion, according to the rest of the face and action; while should the face remain fronting, with the body directly toward the camera, when the eyes turned two or three points away there would immediately appear an uneasy, insincere, jealous, watching expression, not at all pleasant.

"Varying the illustrations by placing the body fronting the third point away from the camera, while the face is turned to the first point, and the eyes into the camera, you will have an easy, direct, sincere, manly attention, while if you place the head and body both pointing to point three, when the eyes are full on the camera you will obtain at once shyness, coquetry, suspicion, or other similar expressions according to the other facial action; then if you point the body on three, while the face and eyes both turn full on the camera, there would begin to appear a bold, domineering, look-you-out-of-countenance sort of expression, or other similar undesirable effects.

"The same principle holds good in looking upwards; for instance, the head slightly raised with the eyes about half as much more may express spiritual contemplation, adoration, supplication, &c., according to the accompaniments, while the face remaining level or slightly drooped with the eyes still turned upward, looking, as they must, somewhat from under the eyebrows, will express a cowardly shrinking, a sinister watching, or suppressed anger, according to the other features."

These hints might be greatly elaborated, but the intelligent beginner will place his camera before the sitter and multiply these illustrations to any extent. The main thing to thoroughly understand is, that in every modification and turn of position these relations of the eyes to the face will express something, and if not controlled to express what is desired may give an expression quite undesirable.

Having briefly glanced at lighting, posing, and expression, let me next say something about the needful apparatus. A beginner will very likely attempt this class of work with his ordinary landscape camera and symmetrical lens, with the result that somehow or other they do not produce pictures that can at all compare with professional work, and very likely they will throw it up in disgust. Experience has taught me that home portraiture requires close study and the employment of accessories which, in nine cases out of ten, an amateur does not possess. First, as to the camera. If you are going to confine yourself to simple heads relieved on a white background like some of the examples I have brought with me to-night, your ordinary landscape camera will suffice; but if you aim at more pretentious work, then a studio camera with its side and top and bottom screws is a necessity so as to get the sensitive plate on the same plane as the position of your sitter. Then, again, the camera stand. Very few amateurs are possessed of other than an ordinary tripod which is no use for indoor portraiture. A good, steady, firm stand, capable of raising and lowering the camera rapidly is another necessity.

Then as to the lens. I find a very prevalent opinion exists that any sort of a lens will do. Some one has said, I forget who, that any hammer will drive a nail, and any lens will take a picture; but no lens will do all classes of work any more than one hammer will. In portraiture a good portraiture combination is a *sine qua non*.

Another matter which may seem of small importance to many is the cap of the lens not fitting properly. When I say not fitting properly, I do not mean too loosely on the hood, but just the right thing; if too tightly vibration is likely to ensue when removing it. Even such little matters as these are of importance. I know from experience how necessary it is to guard against such, for when I acquired a high-priced portrait combination from one of our best English makers, the cap fitted so tightly that it was impossible to remove it without shaking the camera, and many a plate I spoiled through it. The sitter was blamed of course.

Head-rests I never use. I have one, but it is a nuisance. When I get a sitter who cannot keep steady for a few seconds, I adopt some pose whereby a natural rest comes into play.

Get a good background by all means. I prefer what is called empire-cloth stretched on a frame, one side light for vignetted heads, the other side a dark slate colour, and on the top I have two rods nailed, which can carry curtains at either side. I find these curtains very handy, they can be used or not at will.

Hitherto I have said nothing about developments; this, at first, will give a beginner some trouble. The chief point is to obtain proper density. Your negatives must not be too thin nor yet too dense, but just the right thing. It would never do to develop a white satin dress with as much pyro as a dark gown. Experience soon teaches a thoughtful operator. I would strongly recommend beginners to stick to one brand of plates, and let these be as rapid as possible, then practice will teach you how to mix your developer so as to get proper printing vigour in your negatives. I never intensify. Should you happen to over expose and so get your plate too thin, I know of no better way of gaining density than that recommended by the Paget Company—I mean their citrate of ammonia formula. By its use, when all detail is out, development is stopped, but the image already formed is allowed to grow stronger.

And now I come to that much-maligned operation of retouching. I do not care what may be the opinion of those opposed to the use of the pencil, I fearlessly assert that retouching is the professional sheet-anchor in this branch of photography, and I should like to see the studio that could be conducted without its staff of retouchers. Until I took lessons and became proficient in retouching, I was quite cognisant, and so were my friends, that my attempts at portraiture were miserable failures; the moment I understood how to retouch and model my negatives that moment I felt I had entered into a new sphere in photography, and then I saw for the first time I had mastered portraiture.

Not only do I advocate retouching, but I recommend the use of every dodge under the sun to improve not only the negative, but also the appearance of the sitter when going to be photographed. I remember once being told by an amateur who had a very exalted idea of his own art culture, on looking at one of my pictures—it was that of a lady friend who had a very pretty face—after examining it and confessing it was very nice but retouched to death, he thought,

“Do you think so,” I replied.

“Yes,” he answered. “You retouch too much, Armstrong, I think.”

Thereupon I went to my emboard and produced the negative. “Show me the retouching.” He stood amazed, and confessed he would not have believed it! I told him he had something to learn yet.

In this case I had taken the liberty of freely using the puff and powder pot, of doing up the eyes and eyebrows, even going so far as to paint the lips quite in the professional-beauty style; and who shall say my picture was not like the original when she sat down? I often hear it argued that retouching kills the likeness and spoils the texture of the picture; all I can say is, a good retoucher will do nothing of the kind, but, on the contrary, will remove those imperfections in the negative which is necessary to the yielding of a pleasing and faithful likeness.

I am not here to-night to tell my amateur friends how to retouch, but merely to say that it is my humble but honest opinion to be an absolute necessity if you care to turn out pictures which are to be acceptable to your friends and a credit to yourself. Not only do I advocate retouching, but I go further, and say, adopt every means, such as the employment of ground-glass varnish, mineral paper, &c., for the improvement of your negatives and leave no stone unturned to produce results that are pleasing and life-like.

Lastly, as to finishing and mounting. Exercise your own taste in this respect; if you have a leaning to and are fond of enamelled pictures, channel by all means. Very likely the most of your friends will say how beautifully finished, while on the other hand you will occasionally meet with some kind friend who will consider your labour in vain, likening your enamel to his patent leather boots. Taste differs in this respect, and perhaps it is well it is so. I prefer to mount my pictures in optical contact with glass, and to enclose them in the good old cases which were all the rage in the grand old collodion days. We seldom see these cases now; but I have brought a few of them with me to-night just for “and lang syne.” Then, again, there are the metal rims; another very nice way of finishing a picture. These rims are not expensive, and if it is desired to hang up a picture they are the very thing. To an amateur they have their advantages, for when presenting your friend with his

picture, as a rule, he has not the cheek to ask for a dozen, as is often the case when mounted on cards. You can with truth say I do not mount on cards, but if you want a dozen or so, here's the negative, get a professional printer to print them.

The mounting of the prints in optical contact is very easily done, if gone about properly. In 1886 the Editor of THE BRITISH JOURNAL OF PHOTOGRAPHY asked me to contribute something to his yearly ALMANAC, and I sent him a short article on *Optical Contact*, which you will find on page 118 for that year. If you follow out the instructions I give you will find it an easy matter to mount your prints in optical contact.

And now, ladies and gentlemen, I have finished my task. Much more could be written about this fascinating branch of photography, but I have already exceeded the time allowed. I have told you plainly what little I know and what I believe to be necessary to success. If what I have communicated should in the smallest degree be the means of assisting any of my amateur friends to overcome their difficulties, I shall be satisfied, while, on the other hand, if you deem me a bore, give me a back seat at next Convention.

ORTHOCHROMATIC PHOTOGRAPHY.

By C. H. BOTHAMLEY, F.I.C., F.C.S.

(Abstract.)

The subject of orthochromatic photography has latterly attracted considerable attention, and has become of so much importance that it seemed probable that a *résumé* of the results which have so far been obtained might not be without interest to the Convention. It is well known that ordinary photographic pictures have not true “values,” that is, do not represent the various coloured objects with their proper degrees of relative brightness. Yellow, orange, and green objects, which are bright to the eye, are almost black in a photograph; whilst blue, purple, and violet objects, which are comparatively dark to the eye, are practically white in a photograph. The explanation lies in the fact that ordinary photographic plates are very sensitive to blue and violet rays, but are only very slightly affected by green, yellow, and orange rays; whilst the eye is most sensitive to yellow, orange, and green, and is only very slightly sensitive to blue, violet, and red. In order to obtain pictures with true “values,” it is therefore necessary to alter the character of the plate in such a way that its sensitiveness to blue and violet is very much diminished, whilst its sensitiveness to yellow, orange, and green is very much increased.

In 1873, Vogel discovered that the addition of certain dyes to collodion plates makes them very sensitive to orange, yellow, and green, and his results were confirmed by other observers. In 1882-3, Taillor & Clayton took out a patent in France and England for the application of eosine in conjunction with an alkali to gelatine plates, the word eosine being used inclusively. Dr. Eder, of Vienna, has investigated the effect of a very large number of dyes on gelatine plates, the dyed plates being exposed to the solar spectrum. He found that several dyes slightly diminished the sensitiveness of the plates to blue and violet, whilst they increase this sensitiveness to green, yellow, or orange, in a marked degree. Only comparatively few dyes, however, exert any useful sensitising effect. Eosine and its allies and cyanin were found to give the best results.

The author has repeated Eder's experiments with the eosine dyes and cyanin, using the spectrum of burning magnesium instead of the solar spectrum.* His results confirm generally those of Eder, but he finds that a much greater sensitiveness to yellow, &c., can be conferred upon the plates than was observed in any of Eder's published experiments. Plates treated with an aqueous solution of erythrosine or an ammoniacal solution of rose Bengal are about half as sensitive again to the yellow as to any other part of the spectrum, whilst plates treated with an ammoniacal solution of erythrosine are about two and a half times as sensitive to yellow as to any other spectral region.

There are two methods of adding the dye to the gelatino-bromide. In one the dye is added to the melted emulsion, or to the solutions before precipitating; in the other, the dried plates are steeped in an aqueous or ammoniacal solution of the dye. There is, at present, a large preponderance of evidence in favour of the latter, or “bath” process, so far as regards the rapidity and orthochromatic effect of the plates.

The particular dye to be used depends on the nature of the effect desired, since different dyes confer a maximum sensitiveness for different rays. The following list may be useful:—Chrysianiline for green, eosine for yellowish green, erythrosine or rose Bengal for yellow, cyanin for orange and orange-red, coerulein S. for red. For general purposes erythrosine, which is closely related to eosine, is the best, since it confers a maximum sensitiveness for yellow, together with considerable sensitiveness for orange and green, especially if used in ammoniacal solution. Of the many varieties which are in the market the author recommends either the “Erythrosine extra” of Meister, Lucius, & Bruning, or the “Erythrosine 1” of the Badische Anilin und Soda-Fabrik. The method recommended for preparing the plates differs but slightly from that of Mallmann and Scolik, or Eder. The plates employed should be of medium rapidity, since highly sensitive plates are so near the fogging point that the treatment with ammonia and the dye is very liable to carry them past this point. Paget Prize Plates XXX. or Wratten's Ordinary answer very

* For details see the *Journal of the Society of Chemical Industry*, June, 1887, pages 423-433.

well. The plates are carefully dusted with a camel-hair brush and are then soaked for about two minutes in a one per cent. solution of ammonia, drained for a few seconds, and then immersed for about two minutes in the following bath:—

Erythrosine solution (1 : 1000)	1 part.
Ammonia (1 : 10)	1 "
Water	8 parts.

The dish is rocked now and again to promote uniform staining, and the plates are drained with their lower edges on blotting-paper and dried in complete darkness. They will keep for several weeks, but the rapidity falls off somewhat. The above formula will serve for dyes other than erythrosine. Stock solutions of the dyes (1 : 1000) are kept ready prepared; they are made with sufficient accuracy by dissolving five grains of the dye in ten ounces of water.

All operations connected with the preparation and development of the plates should be conducted in as weak a light as possible. Yellow light may be used if extreme care is taken to keep the plates covered up, but it is better to use ruby light, such as is given by a candle behind one thickness of ruby glass or paper. Exposed plates are best developed by means of alkaline pyro tolerably well restrained. All the other operations are conducted in the usual way.

Although the application of the dye increases the sensitiveness to yellow, &c., the sensitiveness to blue and violet remains much too great, and in order to obtain correct gradations it is necessary to diminish the intensity of the blue and violet rays by interposing a transparent yellow screen between the object and the lens, or between the lens and the plate. The depth of tint of the screen determines the proportion of blue and violet which is cut off, and hence determines the relative prominence given to yellow, orange, &c. By properly selecting the depth of screen to suit the subject and the result desired, the photographer is able to exercise very considerable control over the character of his picture. The best form of screen consists of a film of dyed collodion, gummed to the diaphragms of the lens. A yellow dye, such as Manchester yellow, or aurantia, is dissolved in enamel collodion to the required depth of tint, and the collodion is poured on a carefully polished glass plate. When dry the collodion is stripped from the plate and cut into pieces of suitable size. A plate of yellow glass, or of ordinary glass coated with dyed collodion or gelatine, may also be used, and is best cut in the form of a circle and placed inside the hood of the lens—a position in which it does not interfere with the use of cap or shutter. It is essential that the faces of the glass screen be as perfectly parallel as possible, in order that the definition of the lens may not be interfered with.

Treatment with the ammoniacal dye solution increases the rapidity of the plates about three times, but the yellow screen cuts off nearly all the blue and violet, and hence the use of the screen increases the exposure required to twice, thrice, or even ten times that of the undyed plates without a screen, the time depending on the depth of tint of the screen.

In order to illustrate the character of the results obtainable, the author exhibited several sets of photographs of various coloured objects taken (1), on an ordinary plate without any screen; (2), on a dyed plate without any screen; (3), on a dyed plate with a yellow screen. The time of exposure was the same in all three cases, and since the plates exposed without a screen were very much over exposed every chance was given for the yellow, orange, &c., to register themselves on the plates. Undyed plates exposed for the same length of time behind a yellow screen gave no trace of a developable image. Each plate was developed with a view to obtain the best possible rendering of the yellows, greens, &c. The examples shown included photographs of a scale of coloured paper, chromo-lithographs, flowers, pottery, and landscapes. The "values" of the pictures taken on dyed plates with a yellow screen are very satisfactory and are an immense improvement on those taken in the ordinary way. In the case of the flowers and pottery the differences were very marked indeed. When the dyed plates are exposed without any screen the rendering of yellow, green, and orange is very much improved, but blue and violet are far too light. It is only when the yellow screen is used that the values become correct. Care is necessary, however, to avoid cutting off too much of the blue and violet, and thus making the gradations incorrect in the opposite direction. In landscapes the improvement was much greater than was anticipated. It is most marked in the rendering of masses of foliage and of the different shades of green. Moreover, the yellow screen cuts off the greater part of the blue atmospheric haze and thus gives clearer distances.

Many points of detail require further investigation, but it may safely be said that orthochromatic methods place great additional powers in the hands of the photographer and constitute a very great advance in both scientific and artistic photography.

CAREY LEA'S PHOTOCHLORIDE OF SILVER.

By WILLIAM LANG, JUN.

The alchemists of old had their philosophers' stone and elixir of life, and many, indeed, were the attempts made by those early pioneers of chemical science to wrest from nature what they considered would be of untold benefit to mankind. I take it, gentlemen, that if anything in our art is, or can be considered as analogous to the philosophers' stone of the alchemist, we will find it in that branch of photography which has

received the name of heliochromy. Photography in natural colours would indeed be a grand achievement, but the question is, Are we any nearer its accomplishment than we were in 1818, when Becquerel laid before the French Academy of Science his silver plate imprinted with the colours of the spectrum. I think, gentlemen, the position of affairs at the moment is this, if silver chloride is to be the medium by which a transcript of the colours as we see them in nature is to be arrived at, we should very soon now be able to say definitely whether the thing be a possibility or not. As you are aware, there have been many workers in this field. It will be sufficient to recall to you the names of Nièpce do St. Victor and of Poitevin, of Herschel, Hunt, and Abney. Becquerel's work we have already alluded to. One would have thought that by this time all the changes that were possible had been rung as far as production of colour from silver chloride was concerned, but that such is not the case is remarkably evident from the contribution to photographic science that has lately been made by Carey Lea. In the May number of the *American Journal of Science*, the first of a series of papers made its appearance, having for its title, *On Red and Purple Chloride, Bromide, and Iodide of Silver; on Heliochromy, and on the Latent Photographic Image*, and it is some of the facts brought forward by the American experimentalist, not only in the May, but also in the June number of the *American Journal of Science*, that we purpose laying before the members of the Convention this evening. Carey Lea's memoirs are so full of suggestive material that in a communication such as the present one or two points can only be touched upon. Those interested in the chemistry of photography will recognise at once the importance of the researches that have here been carried out. The whole contribution is remarkable for its originality, and it takes its place at once in the first rank of the many classical researches which from time to time have enriched photographic science. Carey Lea's views regarding the latent image may or may not be ultimately accepted by those competent to form an opinion, but the fact remains that his experiments will form the starting point for further investigations. It is no small matter for the experimentalist to be able to produce in the laboratory and in quantity that coloured form of silver chloride which hitherto has only been obtained, and that in what might be termed infinitesimal quantity, on the surface of silver chloride by the agency of light. To the coloured substance thus produced, Carey Lea has given the name of photochloride, and specimens I beg herewith to put forward for your inspection. It is worthy of notice that this photochloride can be obtained by a great number of methods. For these we must refer those interested to the original paper. It will be sufficient for the present to indicate that particular process by which the specimens now before you have been obtained. Freshly precipitated silver chloride after washing was dissolved in ammonia, and to this a solution of ferrous sulphate was added, producing an intensely black precipitate. Dilute sulphuric was afterwards added till a slightly acid reaction was manifest. Thereafter the precipitate was well washed by decantation and boiled with dilute nitric acid, washing was again resorted to, and the product treated with hydrochloric acid dilute, boiled, and finally washed. I show specimens of the substance both in the moist and dry state. I have also prepared the corresponding photo-salts obtained from the bromide and iodide of silver, thinking that they would not be without interest, and here are the specimens of photobromide and photobromide in question. Their mode of preparation is somewhat similar to the method employed in the case of photochloride, but, here again, we must refer members for particulars to the original communication reproduced in our own two leading photographic journals.

To come back to the consideration of the photochloride, the question naturally arises, What is it? Its discoverer describes it as a combination of silver chloride with its own subsalt, but one extraordinary thing connected with it is that no two specimens, although to all intents and purposes prepared in the same way, show the same percentage of subsalt to that of the normal chloride. The amount of the former substance, combined with the latter, seems to vary from half per cent. to something like nine per cent. To quote Carey Lea's own words—"Even when silver chloride, bromide, or iodide contains as little as one-half of one per cent. of subsalt combined, its properties are greatly changed. It has a strong colouration, and its behaviour to light is altered. Even a much less quantity, one inappreciable to analysis, is capable of affecting both the colour and the behaviour to light."

It seems to me that much experimental work will have to be done before a clue to these variations will be satisfactorily obtained. To enumerate all the reactions of this phenomenal compound would simply weary you; one striking characteristic may perhaps be alluded to, and that is its being able to resist for a considerable lengthened period the action of boiling aqua regia. Referring to the colours assumed by this protean substance, Carey Lea specifies that it "shows all the warm shades from white to black through the following gradations: white, pale flesh colour, pale pink, rose colour, copper colour, red-purple, dark chocolate, black."

Another point that will require elucidation before the complete identity of the chloride, coloured by the agency of light, and the photochloride produced in the laboratory be established, and that is, Is oxygen present in the latter substance? Carey Lea says nothing in his memoir that would indicate the presence of oxygen. Dr. Hodgkinson's experiments demonstrate what other experimentalists previously had inferred, that in coloured chloride, produced by light, oxygen is invariably present. I feel

sure we will not have long to wait before an answer will be given to the question here raised.

I think it would be doing Carey Lea great injustice were I not to allude to a discovery he has made, and which is embodied in his memoir, namely, that he is able so to affect a film containing a silver haloid by application of a chemical reagent, that he can produce a result equivalent to the latent image formed by the agency of light. The body which gives this result in the most pronounced manner is sodium hypophosphite. It virtually, according to Carey Lea, converts the haloid into a photo-compound, producing no visible change, but when a developing agent is applied the action is rendered manifest.

At the conclusion of the article which appeared in the May number of the American journal already referred to, we find Carey Lea making use of the following language:—"I am persuaded that in the reactions which have been here described lies the future of heliochromy, and that in some form or other this beautiful red chloride is destined to lead eventually to the reproduction of natural colours." Now, gentlemen, does this language seem too extravagant? For my own part I do not think so. The impossibilities of one age become the veriest possibilities of the next. I do not think that even were we able to depict the colours of nature on the photographic tablet that that accomplishment would transcend in value the fact that we are able now in the merest fraction of a second to record the most rapidly moving object that can be presented to our cameras. At the commencement of my paper I drew, as it were, a parallel between the alchemist of the past and the photographer of the present, permit me to continue it, and should it ultimately be found that a research, such as Carey Lea's, does not lead up to the philosophers' stone of the photographer, does not render possible the reproduction of the colours of nature, still the work he has done will be of lasting value to those interested in the chemistry of the silver haloids. Brewster, many years ago in his letters on Natural Magic, wrote as follows, and I think that what he then said regarding alchemy will show that what after all may turn out to be a dream is not without its beneficial result:—"Though the philosophers' stone has not been found, chemistry has derived rich accessions from its search; though the general solvent has not been obtained, yet the diamond and the gems have surrendered to science their adamant strength, and though the elixir of life has never been distilled, yet other substances have soothed 'the ills that flesh is heir to,' and prolonged in no slight degree the average term of our existence."

Friday's proceedings were rather brief, on account of the dinner, which was fixed for nine o'clock.

The papers read were:—

MODERN FILM PHOTOGRAPHY.

By BUCHANAN WOLLASTON.

In introducing the subject of modern film photography to the notice of the members of Convention, I do so with some diffidence, for I see many gentlemen in the room—old masters of our art-science—to whom any remarks of a poor "junior" in the profession like myself must appear mere foolishness. To them I offer my apologies, in the hope that they will, for the sake of those not yet having attained their majority, bear with me a short space of time in my endeavours to educate the more inexperienced of the brethren; and if, perchance, I may lead some of the "old birds" to a study of this most fascinating branch of the art, it will of course be the more gratifying to me.

It will be my aim in this paper to avoid empiricism on the one hand, as leading simply to photographic quackery, and on the other hand, I do not wish to pose as a dogmatist, because however much I may know—or think I know—about gelatino-bromide films, there will be those coming after me who are sure to know more, and the greater the number of workers and experimenters the more chance of arriving at the nearest approach to perfection allowed to us mortals to attain to.

I do not propose to tire you, gentlemen, with a history of film photography from its first inception, for to the student it is a matter of but little difficulty to arrive at all necessary facts in connection therewith, and I take it that most of us, more especially on such an occasion as this great gathering, would feel inclined to say, "Let us to business," or "D—n the theory!"

It has been said that film negatives will never become popular with the professional landscapeist, but I submit that this is only partly true. There are those gentlemen who will not look into the merits of any new invention—"It is too much trouble," say they, "and we don't want anything better than what we have got." Possibly they may have a nice dogcart in which to convey their *impedimenta*, or a muscular operator who has to bear the burden of the paraphernalia, while the "guy'nor" pockets the results of his exertions. Others say their printer would spoil every negative in no time, and so on.

There are, however, a large section of the photographic community whose pride is to do the best work, without assistance, or with as little as may be, and it is to such men that the advantages of film photography specially appeal, as well as to the amateur.

The advantages are briefly as follows:—1. Portability. 2. Freedom from breakage. 3. Absence of halation. 4. Ease of manipulation. 5. Suitability for carbon printing, and the various photo-mechanical processes involving a reversed image.

No. 1. Portability may be elaborated into:—(a), Storage space: 250 film negatives occupy a space, under slight pressure, of a little more than one inch. A similar number of glass negatives, of average thickness, take up about two feet four inches. (b), Weight: Two whole-plate glass negatives taken at random from a box within six feet of me while I write, weigh fourteen and three-quarter ounces, *nearly*, while two films of same size, also taken at random from an envelope upon the table, weigh exactly five and a half drachms, *avoirdupois*, or stated in grains 6452 apothecary, as against 151.5 apothecary = 42.7 times as much, approximately. Surely this is of great importance to those who place their printing out, to the traveller, tourist, or outdoor operator.

No. 2. Freedom from breakage. What an immense number of valuable negatives are smashed annually, either by "Slipping through my fingers, sir," or in the pressure frames! With films we enjoy complete immunity from these dangers. Further, our negatives may be readily cut with scissors or with a cutting glass to any desired size and shape, without the risk inseparable from the use of the diamond even by skilled hands.

No. 3. Freedom from halation. This is, perhaps, one of the greatest advantages possessed by films *versus* glass, and to those who are engaged in the taking pictures of interiors will it specially commend itself. I have already shown negatives before the Photographic Society of Great Britain in which the delicate tracery of windows and the finest twigs of trees are depicted with almost microscopical sharpness, and these under very prolonged exposure. A slight blurring is noticeable in some instances, which I attribute entirely to diffused light in the camera, not to halation proper.

No. 4. Ease of manipulation. It has been said to me by many of my pupils in photography *before* commencing a set of lessons, "No, I don't think I will go in for paper negatives (or film), it seems so difficult." Now, I have made it my study to find out how this prevalent notion of *difficulty* has arisen, and the result of my investigations lead me to the conviction that in almost every instance either the gentlemen themselves, or some amateur tyro whom they know, has attempted paper or film negatives, vainly imagining that they would behave exactly like glass dry plates. To them I say: "Between film photography and glass dry plate photography there is almost as much difference as between dry plate and wet collodion work, and you must unlearn a good deal of one before you will succeed with the other." It is, then, quite wonderful how the *difficulty* notion slowly but surely gives way before the charm of developing a whole spool of twenty-four exposures in one, two, or three batches, in little more solution than would suffice for three dry plates, and before many days my pupils are led to make such remarks as the following: "Why, the whole thing is as easy as toning a lot of prints;" or, "I can't think why So-and-so made such a mess of his negatives!" There are, of course, those whose "fingers are all thumbs," or who lack common-sense. They had better confine themselves to spoiling dry plate negatives rather than bring discredit upon one of the most beautiful processes of our times by their bungling.

The operation of squeegeeing upon collodionised glass, stripping by means of hot water, attaching the permanent skin, &c., are so entirely new to the average worker that they favour the idea of difficulty, and when one or two negatives only have to be finished, the preparations necessary may be somewhat out of proportion to the advantages, but in making, say, one or two dozen negatives in a batch, the operations subsequent upon development become so methodical and mechanical, and are performed with such regularity and precision, as to make one wonder wherein lies the difficulty so often complained of.

No. 5. Suitability for processes involving a reversed image. Film negatives being printable from either side, it is sufficiently obvious that they are eminently well suited to the requirements of the photo-mechanical printer, the carbon printer (by single transfer), and the collotypist; and as there is but little difficulty in obtaining absolute opacity in bright light with as perfect clearness of shadows as possible, I fancy that engineers, topographers, and others, will ere long open their eyes to this new power placed in their hands. How delightful to have a film negative of large size (say 40 × 36), or a set of such negatives, stored on wooden rollers, ready when required to be used for the reproduction, by any process, of an unlimited number of copies of an original, either right or reversed. Ye manufacturers of films look to this! There are many other advantages which have been mentioned from time to time by various writers to the photographic papers, such as greater rapidity of a given emulsion spread upon paper rather than glass; cost, not forgetting the non-requirement of extraneous assistance, decreased postage and carriage, and non-breakage; the possibility of taking a second exposure of any subject, when at a distance from home and doubtful as to exposure, &c., without running short of plates, thereby saving time, temper, and trouble; the absence of dust on finished pictures, when used on spool in a roller slide; the facility of changing spools where no dark room is available, at the sacrifice of one or two exposures only, and so forth.

I now pass on to the manipulation of the films, prefacing my remarks by observing that, although excellent pictures have been, and are still, and will be, produced on films cut to standard sizes in ordinary dark slides, and prepared by many different methods of manufacture, some very ingeniously held "taut" by mechanical holders, others kept flat by means of an adhesive material, the real utility of, and the greatest advantage arising from, film photography can only be truly appreciated

by the possessor of a roller slide of some design, charged with a spool of sensitive material of sufficient length for twenty-four, forty-eight, or more exposures, to be subsequently cut into the required sizes for development.

Be the roller slide of what make it may, and the film, whether permanently attached to a paper backing for rendering translucent by oil, vaseline, or varnish, after drying, or a "stripper," or any film capable of being made in length, there are certain rules to be followed and certain anars to be avoided which it will be my object to briefly notice.

The method of inserting the spools in whatever form of roller slide the practitioner selects is a matter in which the inventor of that particular slide is likely to be the best instructor, but let me caution the beginner to be careful not to finger the spool of paper more than necessary, and to see that the first exposure is strained *flat*—i.e., without diagonal creases, which I have known follow through a whole spool, and either spoil or considerably mar every picture thereon.

In my own practice I have found films, *ceteris paribus*, more rapid than glass plates, but upon this point I have met with the most conflicting evidence, some experimenters positively asserting that they are slow, others that they are much more rapid than any other form of gelatino-bromide. Now, my impression is that with a given emulsion rapidity is favoured by spreading it upon paper, for three reasons:—(1), That in drying emulsion upon paper no crushing of particles takes place on the lower strata; (2), that no blurring of light into shadow takes place; and, (3), that the developer, attacking the light affected parts on both sides, brings about a more complete reduction of the haloids. But a great secret lies in development, and I shall endeavour to show you how this can be accomplished with success.

Two golden rules: Do not over expose. Push the development further than seems necessary.

Without troubling you with experimental formulæ, I will give you at once the developer I now use and swear by, but if any member will show me a better I will abandon my pet at once upon conviction. My formula stand thus:—

No. 1.

Sodic sulphite, *pure* 8 ounces.
Hot distilled water 40 " (fluid).

Let cool to 60° Fahr., and render *just* acid with citric. Test with litmus. Pour on to 1 ounce (437½ grains) pyro.

No. 2.

Sodic carbonate, *pure* 4 ounces.
Potassic " *pure* 1 ounce.
Distilled water 40 ounces (fluid).

Mix equal parts No. 1 and No. 2 for normal exposures.

Always have a ten per cent. solution of bromide at hand for emergencies, and use if great opacity is desired, but as a rule no restrainer seems necessary.

It is sometimes desirable to proceed with caution, and add a portion only of the No. 2 solution at the outset, and when time is not of much importance I prefer further to dilute the mixed developer with one-third to one-half its bulk of water.

With the above developer and plenty of time—always given a reasonable amount of brains, as Colonel Stuart Wortley once remarked—uniformly excellent negatives can be produced with almost absolute certainty, and upon any of the leading films now in the market; but I must frankly admit that I have seen negatives produced by one of our much-respected members with an ammonia developer fully equal in quality and pluck to the best by my method, but then it is the man, not the developer. In my hands ammonia falls far short of the fixed alkalies in uniformity of results.

It is not within the scope of this paper to give detailed instruction in finishing either paper or film negatives, nor is it my intention to recommend any particular brand, or special roller slide, but I will tell any member who wishes to know—quite privately of course—where lies my love. And if my remarks may induce any gentleman to try filmography and he gets into difficulties, let him write to me and I will try and help him over the stile.

PICTURE MAKING.

By DAVID PRATT.

MUCH that is written on this subject is without value to the inquiring amateur, because, while it goes round about it, it seldom touches to give practical guidance.

This comes from a general impression that a born artist *only* knows what elements make a picture, and he who is *not* thus naturally gifted will only make a picture by chance. It is true that artistic intuition is the power in picture making, and he who is *so* gifted when viewing nature selects by that inborn power what pleases himself and gives pleasure to others. In other words, he is a *poet*, and when he gives expression he strikes a chord wherever the poetic exists.

This is *accepted*; but it is not generally admitted that there are also laws in picture making that may be defined, and the disregard of which makes a pleasurable picture impossible.

We are told that the old masters had a code of laws which got *buried* with them, but their *works* remain to *prove* the laws they recognised.

These laws existed before them, and *do exist now*, superior to our constituted appreciation of them.

These regulate picture making in each of its branches—landscape, sea piece, figures in landscape, figures, colour.

If the mention of a few of these laws will start inquiry this short paper will not be in vain. 1. The chief object away from the centre. 2. The greatest light against the greatest dark, or the reverse. 3. One-third light and two-thirds dark, or the reverse. 4. The odd set of chords, three or five. 5. If three chords of light or shade be adopted, the one should not be equal to the other. 6. The unequal line or curve of beauty. 7. The odd number of figures. 8. One prominent harmony of colour, or contrast in light and shade.

Let these suffice for the present purpose. A successful picture *may* be made by the intuitive power *although* these laws have not been acknowledged, but we maintain *fewer* mistakes will be made by a full recognition of them.

While chemical and mechanical manipulation is making great strides, and we are seeing beautiful workmanship on every hand by the discovery and recognition of laws regulating these sciences, it only becomes us to formulate the laws of picture making by a careful study of them.

THE CONVENTION DINNER.

After the close of the last General Meeting, on Friday night, about fifty of the members met at the "Bath" Hotel to partake of an excellent dinner. After the removal of the cloth the following programme was gone through:—

Toast: The Queen, by John Stuart.

Song: "Tom Bowling," by Andrew Pringle.

Toast: The Amateurs. Proposed by Jno. Henderson, of Perth, and acknowledged by P. Falconer (President Glasgow Amateur Association).

Recitation: "A Scotch Story," by Jas. Davie.

Toast: The Professionals. Proposed by J. Traill Taylor; acknowledged by W. H. Prestwich, of London, John Fergus, of Largs, and — Moran, of Glasgow.

Toast: The Convention. Proposed by W. Lang, jun.; acknowledged by Jerome Harrison, of Birmingham.

Song: "Since we were Boys together," by T. N. Armstrong.

Recitation: "The Braw Hielan' Bagpipes," by J. Henderson.

Toast: Photographic Societies. Proposed by Jno. Stuart; acknowledged by Prof. Herschel.

Song: "Jack's come Home to-day," by Geo. Mason.

Song: "The Drygate Brigg," by A. Bowman.

Recitation: "The Bell and the Ivy," by S. D. McKellen.

Song: "The Lowland Bonnet," by Andrew Pringle.

Recitation: Burns' poem "The Louse," by Jno. Urie.

Song: "The Braw, Braw Clerk in the Offish," by — Reid.

Concluding with "God save the Queen," and "Auld Lang Syne," sung hand-in-hand by the whole company in true Scottish fashion.

It would be almost vain to hope to give any of our readers—except those who were present—an adequate idea of the good-fellowship and joviality which prevailed. Suffice it to say that Mr. Pringle's "Bonnet" song (with illustrations) was alone worth a journey across the Tweed to hear.

A Meeting of the Council was held in the "Waverley" Hotel on Saturday morning, at eleven, J. Traill Taylor in the chair.

The following new members of the Council were elected:—Prof. Herschel, Messrs. W. H. Walker (Eastman Company), Tate (Belfast), Bothamley (Leeds), McDougal (Dundee), T. N. Armstrong (Glasgow), and Dr. H. H. Norris, Councillor Lancaster, Messrs. J. Place, J. H. Pickard, B. Karleese, Whitlock, John Collier, and Harold Baker (Birmingham).

Letters were read from four photographic societies appointing, as their representatives on the Council, the following gentlemen:—C. H. Bothamley, F.C.S. (Leeds), R. Keene (Derby), J. C. Cox (Dundee), and — Illingworth (Halifax).

The following Sub-committee was appointed to draw up the rules and regulations by which the Convention should be governed:—Messrs. J. Stuart, W. H. Walker, W. Jerome Harrison, Andrew Pringle, Smith, and Wollaston, together with the Chairman of Council and Honorary Secretary as *ex-officio* members.

A vote of thanks was given to Bailie Morrison for the loan of various articles used in the Exhibition.

Votes of thanks were also passed to the Edinburgh Photographic Society, to the Hon. Secretaries (Messrs. J. J. Briginshaw and Jas. Davie), to the Chairman of the Council (J. Traill Taylor) and of the Local Committee (John Stuart), and also to the leaders of excursions, and the local Sub-Committees.

These pleasant duties performed, the Convention was in imminent danger of becoming wealthy, as one gentleman after another got up to offer donations of five and ten guineas. It was decided, however, only to accept these in connection with the establishment of a Guarantee Fund.

After the Council meeting several of the members inspected the splendid studios, &c., of Mr. Turnbull, in Jamaica-street; while others paid a parting visit to the quays, detective cameras in hand. But the time to part soon came, and with hearty wishes for "our next merry meeting at Birmingham" the party separated, some to the Highlands and the Lochs, others to yachting, but the majority back to their daily avocations, bearing with them pleasant memories of a week charged full of pleasure and instruction.

THE EXHIBITION DEPARTMENT.

We here summarise the exhibits, which were very numerous:—

Houghton, London: Studio tent, portmanteau sink, negative and film washing trough, dark-room developing sink.—*Launcester & Son, Birmingham*: Cameras, lenses, stands, &c.—*G. Mason & Co., Glasgow*: Lamps, cameras, papier mache trays, studio stands, large American cameras, &c.—*Albion Albumenising Company, Glasgow*: Studio camera and studio stands with compensating balance arrangement, portable cameras, 12 × 10, 10 × 8, negative washing troughs, lamp, &c.—*McGhie & Bolton, Glasgow*: Cameras, stands, &c.—*Place, Birmingham*: Shutters, &c.—*Wollaston*: Shutters.—*Moryson, Dumfries*: Patent show-case for photographs.—*Watson, Laidlaw, & Co., Glasgow*: Emulsion separating machines for A. L. Henderson.—*York & Son, London*: Two frames of lantern slides.—*Underhill, Croydon*: Lantern slides.—*F. W. Verel & Co., Cathcart, Glasgow*: Two fine photographs done on their plates.—*J. Urie, Glasgow*: Patent auto-printing machine and specimens done by it.—*Pollard, Graham, & Co., Derby*: Negatives and transparencies.—*S. Fry & Co., Kingston-on-Thames*: Bromide enlargements, &c.—*Morgan & Kidd*: Bromide enlargements and film roll holders, &c.—*Tylar, Birmingham*: Metal slides.—*Watson & Son, London*: Cameras, stands, &c.—*Shew, London*: Detective cameras, universal camera, clips for yachts, &c.—*McKellen, Manchester*: Cameras, &c.—*Wollaston*: A stereoscopic shutter.—*Ross & Co.*: A case of lenses.—*Sharland, London*: A detective camera.—*Taylor, London*: Two American detective cameras, and a specimen of Mayall's coloured photographs.—*T. & R. Annan, Glasgow*: Photographures, autotypes, Sir Noel Paton's *Fairy Raid* on large opal, machinery, &c.—*John Stuart, Glasgow*: Autotype and bromide enlarged portraits, machinery, &c.—*Turnbull & Sons, Glasgow*: Large show-cases of photographs.—*Maenab, Glasgow*: Very large assortment of photographs, platinotype, bromide enlargements, silver prints, &c.—*Valentine, Dundee*: Views, &c.—*Oliver, Glasgow*: Transparencies.—*Murray, Glasgow*: Landscapes, portraits, &c.—*W. Suell Anderson, Glasgow*: Landscapes, portraits, &c.—*Donald Done, Pollockshields*: Views, &c.—*Alex. McDonald, Arran*: Views, &c.—*W. M. Martin, Dundee*: Views, &c.—*Mathewson, Dundee*: Views, &c.—*Brown, Paisley*: Photographs.—*R. Keene, Derby*: Platinotypes, &c.—*Wm. Crook, Edinburgh*: Enlargements, portraiture.—*R. T. Dodd, Glasgow*: Portraits.—*Wm. H. Glen, Derby*: Photograph.—*Charles Reid, Wishaw*: Studies of animals (specially good).—*H. Bolden, Derby*: Derbyshire scenery in platinotype.—*Bothamley, Leeds*: Specimens of orthochromatic photography.—*T. McGown, Paisley*: Carbon enlargements.—*J. McDonald, Gareloch*: Landscapes.—*J. Rennie, Helensburgh*: Landscapes, &c.—*Buchanan Wollaston, Chislehurst*: Film negatives, &c.—*G. Mackenzie, Paisley*: Carbon enlargements.—*J. Milne, Arbroath*: Portraits.—*J. G. Tunny, Edinburgh*: Enamel miniatures, &c.—*Wm. Lang, jun., Glasgow*: Eight frames of photographs (various).—*John Parker, Glasgow*: Views.—*Daniel Frazer, Glasgow*: Views.—*Cox, Dundee*: Figures and views, &c.—*Wm. Goodwin, Glasgow*: Views, &c.—*Ralston & Sons, Glasgow*: Carbon enlargements.—*Alexander Bros.*: Painted miniatures, &c.—*Hugh Reid, Glasgow*: Views, &c.—*T. N. Armstrong, Glasgow*: Views, &c.—*P. Falconer, Partick*: Views, &c.—*J. B. Willington*: Views.—*Ralph Elder*: Views.—*Archibald Watson*: Views.—*Dr. Bell*: Views.—*R. Dalglish*: Photographs in 1859.

We now proceed to give a more detailed account of some of the exhibits.

One of the most interesting, from an educational point of view, was a case of lenses by Ross & Co., London. It showed the history of one of their rapid symmetricals from the raw material up to the finished instrument. First, in this evolutionary process of mechanical art there were the rough brass castings before they were touched by the brass worker; and in harmony with these there were the crude pieces of optical glass, as yet unseen by the lens grinder. As the next stage, there were what had once been similar pieces of glass, but now they had been rough ground into lenses, both convex and concave. A third stage showed these lenses finished with an exquisite polish, but not yet having the elementary parts cemented together with balsam. Another portion of the exhibit was more interesting

still, for it was a lens complete in its mount, but bisected from end to end by a thin saw, the section showing the whole configuration of the lenses, brass work, diaphragm and flange, each in true relation to the other. The last item in this collection was a completed lens ready for being screwed on the camera.

C. Wollaston's diaphragmatic shutter is now pretty well known. Its principle consists in the opening and closing being effected directly opposite the centre of the lens, with an adjusting screw by which the exposure can be so regulated as to be either very rapid or protracted to any desired extent. A new departure, which was exhibited, consists in having the levers, shutters, and other fittings in duplicate, so as to be employed in stereoscopic photography, both shutters working with absolute simultaneity, whether fast or slow.

A camera of the *genus* detective, although named the "Compactum," was exhibited by H. Sharland, London, the manufacturer. It is devised by T. Samuels, who exhibited it, or one like it, at the Photographic Society of Great Britain only a couple of months since. It is undoubtedly the smallest detective camera—not a mere toy—that we have yet seen, the dimensions being eight and three-quarter inches long by four and a quarter by five inches in width and depth. Modest and unassuming in appearance, it can be carried in a wrapper of brown paper or be stuffed into the pocket of an overcoat, and yet it contains a dozen sensitive plates, each capable of being brought to the front, one after the other, with singular ease. The focussing arrangement of the lens is what we would designate, without regard to the niceties of nomenclature, a fixed adjustable one; that is, when a movable lever is brought to a certain mark everything between thirty feet and infinity is sharp. Moving the lever to another mark, the point of best focus is brought ten feet nearer, and so on till the object to be photographed is only five or ten feet distance. When a "shot" has been fired a button outside of the camera is run up in a groove and the exposed plate in its sheath is immediately raised, so as to be grasped by finger and thumb through a thin yet opaque protecting bag and transferred to a receptacle behind the others, the next in order assuming its place at the focal plane. When introduced commercially this "Compactum" will prove a favourite.

The "Scovill American," another form of detective camera, was also exhibited and received much commendation. As it is so recently since we gave a full description of it we refer our readers to page 307 of our issue for May 20. At one of the excursions, that down the Clyde to Tarbert, that same camera is known to have done some good work in the hands of its owner, who was the exhibitor.

An ingenious chronometric shutter, which, being in its elementary condition, was not considered as suited for the more public form of exhibition, was shown us by its inventor, Mr. A. Johnston, of Wick. It merits, however, special mention. Perhaps the term "chronometric," which is of our own application here, scarcely conveys a correct idea of its nature. This, however, will be seen from the following:—A common cheap watch movement, which can now be purchased everywhere for one or two shillings, has fitted upon its centre wheel or its "cannon pinion" (that which carries the long or minute hand) a disc of brass, having in it a deep notch. Pressing against the periphery of this disc is the end of a lever, which when the determined number of minutes have transpired falls into the notch of the disc and releases the catch of the shutter, which gives the exposure. One use of this system is to be found in connection with captive balloons; but it is applicable to anything in which a determinate degree of time is to elapse between the setting of the shutter and the instant of exposure. Our readers will not be slow in imagining many cases to which it might be applicable. Being at present in our office it may be seen on application.

A detective camera by Messrs. E. & H. T. Anthony & Co., of New York, claimed attention on account of its ornate appearance. It is elegantly covered in alligator skin. But as the manufacturers have kindly favoured us with illustrations of their Detective, we shall here make use of them in order to convey a clear idea of the instrument.

In outward appearance and to the ordinary observer this camera looks exactly like an alligator hand satchel that is carried by a

shoulder strap at the side of the pedestrian. Upon closer observation one sees that it consists of an artfully concealed detective camera, in which all the various movements to secure a picture are situated upon the under side. For use the camera is held so that the base of the satchel rests against the body of the operator. By means of a brass pull at the side the shutter is set. A plate in the regular holder is placed in position at the back of the camera, and the slide is drawn ready for exposure. The release of a short catch exposes the front of the shutter ready for action, and by raising a small leather-covered lid the little camera obscura called the finder, on the (now) upper side of the camera, shows the position that the object will occupy on the plate. The slightest touch upon a small brass button releases the shutter, and the exposure is made. Replacing the slide in the plate holder, reversing the holder, and setting the shutter again, leaves the apparatus in readiness for another shot, when the plate-holder slide is withdrawn as before.

By releasing a spring bolt on the under side of the case, the camera proper can be removed from its cover. When removed from the cover the camera can be used either vertically or horizontally on a tripod, by means of a tripod screw, which will be found in the front compartment of the camera beside the lens. The speed of the shutter can be regulated to suit the speed of the objects, moving with greater or less velocity; while, by simply releasing a catch, time exposures can be made at the will of the operator.

The cut (Fig. 1) shows the camera when laid on its side, and the

Fig. 1.

under portion exposed to view. When placed on its bottom, and the outer cover or satchel is raised, the appearance presented is as shown in Fig. 2.

Fig. 2.

The reference to the various letters may be omitted here, as these mainly have to do with details of manipulation. But we may allude,

with a high degree of commendation, to that marked in Fig. 1 as H, the index finger of which represents, when set to any particular figure, the distance at which everything is in best focus. H, we need scarcely say, really represents the axis of a large pinion which is geared in a stationary rack. The finder differs from others that we have seen, inasmuch as it is composed of a tiny camera, with a ground-glass placed at a right angle to the axis of the lens, and the image is observed by means of a mirror set at an angle of 45° outside the focussing screen. The duration of exposure can be regulated to a great nicety. It accommodates one dozen of plates, and altogether contains many points of great ingenuity. The exhibitor will also show it at some of the London societies.

The camera, when detached from the satchel, presents the following

appearance: The dark slides, as will be seen, are accommodated in a separate case forming part and parcel of the whole.

(To be continued.)

CONVENTION JOTTINGS.—II.

(By our Special Correspondent.)

THE members of the Convention residing at the greatest distance from the place of meeting came flocking into the city first. On Saturday, Sunday, and Monday, there was a continual stream of cameras, tripods, boxes, and knapsacks peculiar to the wandering portion of the art-science professors, the possessors of which could be seen jogging along carrying their traps, or seated in cabs with their legs, &c., all spread out over the top of the vehicle, as they made for the various hotels.

On Monday a considerable quantity of work fell to the share of the Exhibition Committee, owing to the exhibits in many cases being so late in coming to hand. This is a thing that ought to be noted, and avoided at future meetings. All exhibits should in common fairness arrive some days before the opening of the exhibition, so as to allow of justice being done to all. So great was the press on this occasion that another room had to be arranged and fitted for pictures and apparatus, at which arrangement Mr. R. Turnbull was again to the front. To the credit of the late exhibitors themselves, however, it must be stated that they were both ready and willing to lend a hand, and toiled their level best to help on the hanging and filling up of their exhibits. All was in perfect order to receive the visitors before the hour of meeting.

The walls of the three halls were covered with pictures, and round the doorways were draped flag decorations, so that on entering the whole suite of rooms were at once seen, and the general effect was pleasing to the eye and had a decidedly imposing effect. The crowd of ladies and gentlemen streamed in till the place was filled.

At eight o'clock Bailie Crawford, as already narrated, took the chair, in place of Sir James King, who had arranged to open the proceedings, but at the very last moment he had unfortunately been called away on business to London.

A very excellent Chairman Bailie Crawford made, judging by the pleased, attentive, applauding audience that listened to his opening address; after which Mr. J. Traill Taylor gave an outline of the proceedings for the coming days, and stated that he had received some eighteen papers, so that there was plenty of work on hand for the evening meetings during the week of the Convention.

At this *conversazione* a part of the time was taken up by the ever popular lantern, presided over by the ever genial Mr. Andrew Pringle. He is always good fun, and when during the entertainment the voices out of the dark, which are always there, insist upon "knowing, you know," like Miss Dartle, he tells them you know, like himself. And he never needs to loaf around amongst his papers for his replies; he

carries them always ready away in his head somewhere. You can easily understand this part of the entertainment was a great success.

The first two excursions left Glasgow on Tuesday morning, and they were both well attended. That under the conductorship of Mr. George Bell, for the Falls of the Clyde, left the low-level station at eight o'clock a.m. for Hamilton, where they arrived after a railway run of about thirty minutes.

Here they found brakes waiting on them—one *brake* more than they wanted, and that was a break in the weather that had come round uninvited, and stayed with them pretty well all day. I was not there, but Mr. Bell informed me that the rain came pouring down so that the party agreed to leave out Tillietudlem Castle, and drive on to Stonelufers—the first of the falls. This, he says, is not a good fall from a photographic point of view. As for the visitor with limited time, there is only one point at which a view can be made, and at this point only one can take the picture at a time, so that if there are many about they have to wait their turn. From this place the party drove on to Lanark, arranged about dinner, and to fill up the intervening time drove on to the falls of Cora and Bonnington, and oh, didn't the elements revel here!—thunder, lightning, and rain—the weather clerk was evidently serving up samples of all kinds that were going to Mr. Bell to see which would suit his friends. It is marvellous to find, however, how much enjoyment can be extracted from a combined lot of light spirits, even supposing the weather was *slightly heavy*. The jokes that would not be suppressed passed along as the party had themselves posted up against the shelving rocks, to dodge the pelting showers that passed over their place of shelter. A fisherman, who was fishing in the river, was rather put out at so many tubes aiming and shooting at him, but when Mr. Bell told him that the party were photographers that had come from all parts of the three countries, and that his portrait would be seen in their pictures all over the world, he drew himself up, and looked mightily pleased, and posed to do credit to his country. After an enjoyable dinner at Lanark, some of the party returned to Hamilton, and others took train direct to Glasgow, highly pleased with their trip, in spite of the show of combined elements. This was the only trip that experienced anything like adverse weather during the week.

The Aberfoyle and Trosachs trip took place on the same day as the above. It was highly favoured from a meteorological point of view. Save for one shower, the day was beautiful.

Here a word may not be out of place regarding the returning of the cards which was sent to all members to fill up showing the trips they intended going by. Out of all cards sent out only twenty-five per cent. were returned, and hence the conductors were left in a sorry plight how to arrange, as special railway carriages were wanted and brakes had to be gathered together at the other end of the railway journey, the party anticipated being much too large for the usual conveyance accommodation on the route. Great credit is due to Mr. Armstrong for the masterly way he met the difficulties in connection with this excursion, and the time and trouble expended in arranging the same. Why, the probable number was quite a conundrum, and he guessed it very neatly.

Arriving at Aberfoyle, the land of the bold Rob Roy, and the scene of the famous encounter of Bailie Nicol Jarvie with the wild Highland gillie (for particulars see Scott's *Rob Roy*), the party divided, some going to Loch Ard, but by far the greater number embarking in waggons for the Trosachs and Loch Katrine. As we commenced the ascent of the mountainous slopes by the new private road made by the enterprise of the Duke of Montrose, and while proceeding slowly to enable our thoughtful chaperon, Mr. Armstrong (who remained at the inn until the last of the party had left) to overtake us, it was a scene not soon to be forgotten, to witness the stopping of the cavalcade by a bronzed daughter of these high altitudes, who demanded toll before she would permit us to penetrate farther into the mountain fastnesses. At this juncture the plucky Secretary of the North London Photographic Society leaping from the vehicle, approached the virago and shouted, "You drive on and I'll hold the woman." Oh, for a detective camera at that moment! But a word from Mr. Armstrong, who then approached, quelled the impending storm, a smile chased away the frown, and shaking her fist good-naturedly at her would-be assailant, the custodian of the waggon road wished us all a pleasant journey.

The charm of that run from Aberfoyle to Loch Katrine is indescribable. The wild beauties of nature came into view picture after picture, filling the eye and the soul. Mountains, lochs, tourists, and dales, ever changing, far as the eye could reach, and the broad shifting patches of sunlight playing at hide and seek as they move on from promontory to promontory, and we settled ourselves down to enjoy to the full these charms of nature's choicest gifts.

As we were leaving the conveyances to walk round in search of

likely places for the best pictures, one of our party was accosted by a beggar woman, to whom he gave some coppers. The gift being beyond her anticipations, she was very profuse in her thanks, and exclaimed, "God bless you, sir! may you and yours be in heaven this night."

"Well!" he replied with a laugh, "I have no objections to the place, you know, but please don't be so particular about the time."

"Will you take a drap?" said one of our party to a Highland man he saw sitting at the stream.

"Oh, yes, sir; she'll tak' a drap. This water, sir, can stand an awful lot o' whusky—it's guid water," and pouring out most of the whisky into the cup, he put very little water into it, and took it off at one gulp, proving by demonstration that the water could stand a lot of whisky, then handed back the nearly empty flask with thanks.

The busy scenes being enacted amid these mountain gorges reminded me of a somewhat similar experience of more than ten years ago (see *Noctes Washingtonia*, in *THE BRITISH JOURNAL OF PHOTOGRAPHY*, vol. xxiii., page 501), and finding my old friend "Mungo" lollying under the shadow of a rock, we lighted our pipes and recalled those days of yore, singing together his song of 1876 with immense satisfaction, he adding to it a continuation he had just finished *appropos* of the present Convention. I here give them both, as *impromptus* of brother "Mungo."

THE CAMERA-MEN OF 1876.

O'er brake and through dell, by wood, copse, and fell,
In cool glint, in burnie, and glen,
Where Scotch bell and fern dress boulder and cairn—
Views worthy our Camera-men.

The sun in the vale is gleaming, gleaming;
Each hero keeps working his cell;
I, 'mongst the clover, lie dreaming, dreaming,
Enjoying myself full as well.

The sun sheds his rays o'er hills and o'er braes.
A glimpse of McEidin just then
I caught through the trees, as some object he sees
That is worthy the Camera-men.

The sun in the vale, &c.

Wi' dry plates and wet, they hurry to get
Impressions of lake, hillock, and fen.
What's that glad sound in the air all around?
'Tis the song of the Camera-men.

The sun in the vale, &c.

With silver trimmed sheen, nature dressed in bright green,
And the murmuring, gurgling glen,
Are gems of delight to the sons of the light—
Rare studies for Camera-men.

The sun in the vale, &c.

And thus all the day—half work and half play—
With a few minutes rest now and then,
From the land of the Scot bright impressions were brought
That will live with our Camera-men.

The sun in the vale, &c.

CONVENTION, 1887.

We had that last show a long while ago—
In years it is numbered by ten—
When, on classic ground, the brothers moved round
To the march of the Camera-men.

The sun in the vale, &c.

The sun it has set on the days of the wet,
Familiar to all of us then;
Now, dry paper and glass move on through the pass
In this march of the Camera-men.

The sun in the vale, &c.

We've no bath and no tent, when on pictures bent—
An advantage of now over then—
Our portable kits lick the old ones to fits
In this march of the Camera-men.

The sun in the vale, &c.

A week I'd enjoy, in this land of Rob Roy,
And not feel content even then,
Were the feelings expressed by the brightest and best—
The rollicking Camera-men.

The sun in the vale, &c.

All around the loch, made famous by Scott's *Lady of the Lake*, we enjoyed a good time picture making in the midst of scenes so grand, profuse, and varied—scenery of its kind not to be surpassed in the world. We would have over twenty cameras with us, and had

the advantages of a fair day with little or no wind, so that the workers had every opportunity of procuring fine effects. Mr. Armstrong, who had been over this ground many times previously, took the visitors to the best places for pictures, and thus saved them no end of trouble looking out for them themselves. When we were ready to start home again, a few of the company like sheep had gone astray, and considerable hunting over the place had to be done before we got the lost ones gathered together. Over the hills we came at a spanking rate, and were just in time to reach the station before the train starting time.

In a half-sleepy state, as we were spinning along in the train, I could hear the indefatigable Alexander propounding the following conundrum:—"If the aperture opening of the diaphragm was $\frac{1}{16}$, and the speed of the shutter was one-hundredth part of a second, and the object to be taken was forty feet—no—say twenty feet from the camera, what movement would take place during exposure if the moving object was going at —" They all took out paper and pencil and started to work it out. I fell asleep, for—

"Ta Hielan' hills are high, high, high !
Ta Hielan' lochs are long ;
An' oh, my frien's, ye'll all agree
Ta Hielan' whusky's strong."

" 21	London and Provincial	Mason's Hall, Basinghall-street.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

ON Thursday night, July 7, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. F. W. Cox presided.

Mr. John Warwick Wharton was elected a member of the Association.

A question in the box asked what conditions governed the obtaining of the maximum of detail in the shadows of prints upon albumenised paper.

Mr. A. COWAN responded that it depended upon the negative and not upon the printing.

The CHAIRMAN thought printing in subdued light to be a favouring condition.

Mr. W. M. ASHMAN said that with a very dense negative full of contrast and detail the paper should be prepared upon a weak silver bath, to avoid bronzing in the shadows; if ready sensitised paper is used it should first be floated upon distilled water, to wash off the silver to some extent. Once he had to print from a negative of great importance, but full of the most violent contrasts; it was very dense, taking nearly a week in the printing frame; he accordingly floated his albumenised paper for ten minutes upon a silver bath, thirty-five grains to the ounce, then he washed it by floating upon distilled water. After exposure for about a week, and by the aid of a lens bringing out detail in the densest parts by concentrating the light upon those portions, he succeeded in printing all the detail contained in the original negative. In using the lens it is necessary not to concentrate the sunlight too much or the negative may get cracked with the heat.

Mr. W. H. HARRISON remarked that the Photographic Society of Donai had initiated steps which might lead to the organizing of an International Congress of Photographers in Paris at the time of the Exhibition there in 1889.

The CHAIRMAN thought that such a meeting in Paris would be hailed with pleasure by English photographers.

Mr. ASHMAN hoped the corresponding members of the Association in Paris would keep the Association promptly informed about all steps taken in the matter.

The CHAIRMAN thought that the subject should be revived at a subsequent meeting, when so many members of the Association were not absent at the Glasgow Convention. He should like to know how to remove silver stains from negatives.

Mr. MOUL said that rubbing them with alcohol would take them out when they were just beginning and were very slight.

Mr. ASHMAN stated that Mr. Robertson, of Dundee, had said that if an organic salt of silver had been formed, treating the negative with a sulphocyanide followed by hypo would effect the removal; he (Mr. Ashman) had never met with any photographer who had succeeded in so doing, but if the plan were workable it would be very valuable. He had been asked if gold size varnish could not be applied with advantage to film negatives. Mr. Bridge had published that it answered perfectly, and rendered the films transparent at the same time.

The CHAIRMAN, in the course of a discussion about vaseline and varieties of paraffine, said that he knew that paraffine oil would promote the growth of hair, for some had been spilled over a cat of his; at first the hair came off where the paraffine fell, leaving a bare skin, afterwards it grew again in those places, but thicker than before. It had been said at the Photographic Club that one photographer used a cat as an actinometer, and judged the intensity of the light by the size for the time being of the pupil of the cat's eye; if the pupil were but little contracted it was not a good day for photography.

Mr. MOUL and Mr. ASHMAN said that some of the most popular prints of wild animals in the market had been copied from greatly enlarged negatives.

Mr. HARRISON asked how Anschutz produced the scenic surroundings and backgrounds to his photographs of wild animals.

Mr. EDGAR CLIFTON had been told that Anschutz placed himself in a kind of a cage which was put into their dens, and that the backgrounds and accessories were fitted up in the dens.

The CHAIRMAN had been told that Anschutz had been trying without success for six months to obtain such pictures as he required of the lions, and at last obtained a number of good photographs of them in the desired attitudes all upon one day.

Mr. ASHMAN, in reply to a question, said that the fault of isinglass as a substitute for a commoner gelatine in photography was that plates prepared with it had a great tendency to frill whenever they came into contact with any aqueous solution. In reply to another question, he said that he had found that lactates often proved useful in sensitive surfaces for photographic printing.

Mr. HARRISON imagined that ferrous lactate might be useful for developing; it kept well both in crystals and in powder, and was soluble in water, which, however, would only take up a few grains to the ounce.

The meeting then broke up.

CAMERA CLUB.

THE results of the first year's working of the above Club were before the members at a meeting held on June 16. The present prospects of the Club are most encouraging, and the number of members is rapidly increasing. Owing to the Club having been started with comparatively few members (two hundred), to the exceedingly heavy opening expenses, and to its having been carried on for fifteen months on twelve months' subscriptions, a loss was incurred on the working up to December, 1886; but with the present membership, three hundred and forty, the financial position is most satisfactory and promising, and there is every reason to expect that the Club will steadily develop as a centre of attraction for the amateur photographic world.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

At the meeting held on Tuesday, July 5, at Myddelton Hall, Islington, N., Mr. Alexander Maekie, Vice-President, in the chair, Mr. N. P. Fox was elected a member of the Society.

The CHAIRMAN announced that, in the absence of the Hon. Secretary, who, with the President and several other members of the Society, was attending the meeting of the Photographic Convention at Glasgow, Mr. F. W. Cox had kindly consented to officiate as Secretary.

A number of prints from negatives taken at the Jubilee outing at Watford on June 21 were exhibited by Messrs. Liddle, Piesker, and Walker.

Mr. A. P. Higgins showed prints from negatives taken in Spain, among them a very interesting instantaneous view of a bullfight at Malaga.

Mr. N. P. Fox passed round views of the Jubilee decorations, taken at four a.m. on June 22.

Mr. J. Jackson exhibited a stereoscopic transparency on a collodio-bromide plate. In toning it with gold it had become stained in the sky of both halves. The effect produced was, however, very pleasing, the appearance being that of a vivid sunset in natural colours.

Mr. WILLS passed round a negative which showed a silver stain caused by contact with albumenised paper while damp. He wished to know if the stain could be removed.

The CHAIRMAN said it was an important question, as it was an accident to which everyone was liable. His experience was that the same remedy would not prove efficacious in every case. When the stain was recent and had not penetrated far into the film, rubbing the spot with a piece of rag moistened with turpentine would sometimes remove it; in other cases he had found a solution of cyanide of potassium useful.

Mr. JACKSON objected to cyanide of potassium, as it reduced density too much.

A MEMBER said it had been suggested that for this purpose the cyanide should be dissolved in spirit instead of water.

Mr. OAKLEY had found a strong hypo bath remove the stain without injuring the negative.

Mr. E. CLIFTON had been successful rubbing with a rag moistened with spirit.

Mr. HIGGINS having shown and explained the working of a Durnford's right-about-turn shutter, an interesting discussion took place on the merits of and objections to shutters of various types.

The CHAIRMAN said that to be perfect a shutter should open and close in no time, so that the full amount of light capable of passing through the lens should act on the plate during the whole of the exposure. This was, however, practically an impossibility except in the case of a shutter working close to the plate.

Mr. JACKSON said he had tried many forms of shutter but preferred the

simple drop form working close to the diaphragm. The shutter he used was of metal and he regulated the exposure by means of a longer or shorter drop.

Mr. CHUAN found that in using Lancaster's rotary shutter there was a jar which caused a blur.

Mr. CLIFTON thought the jar occurred in releasing the disc. The spring of the catch was generally too strong. If this were made to work easily and a firm stand used he thought the trouble would not occur.

Mr. Cox having exhibited a platinum print in which clouds were printed in, there was a discussion on printing-in skies and combination printing generally.

Mr. CLIFTON said that a method of combination printing which was particularly useful for printing figures into landscapes or printing landscape backgrounds to figures, had been originally adopted by Mr. Edge and subsequently by Mr. E. Dunmore with great success. In printing a background to a figure, for instance, the whole of the negative except the figure was blocked out, a print from this giving the figure on a white ground. The figure on the print was then painted over with ordinary gamboge water colour, which was allowed to dry. When dry the print was adjusted to the required position behind the landscape negative and printed in the usual way, those parts covered with the gamboge, being protected from the light, not being acted upon. The print was then fixed in the usual way, the gamboge being gently sponged off in the first washing water.

The proceedings terminated with a vote of thanks to Mr. Cox for acting as Secretary.

Next meeting, Tuesday, July 19. Subject to be announced. Outing on Saturday, July 16, to Buckhurst Hill. Train from Liverpool-street at twenty-five minutes past two.

Correspondence.

THE LATE CONVENTION.

To the Editors.

GENTLEMEN,—Being one of the crowd who attended the Photographic Convention of the United Kingdom, held in Glasgow last week, I wish, through the medium of your paper, to express to our Northern hosts my appreciation of their great kindness, shared in by all who were there to partake of the hearty welcome and generous hospitality shown to us by our amateur and professional brethren of Glasgow and Edinburgh. The arrangements made by the various local committees for the Convention, and the members who attended were simply such as to command our unqualified approval and imitation.

The great success of the second Convention is mainly due to the zeal with which our Scottish brethren made and carried out the details. No one knows, but those concerned, the work this implies. I trust the success achieved by our Scotch friends will act as an incentive to the English members, and rouse their enthusiasm, so as to make the next Convention (to be held in Birmingham) even a greater success. I have only to add that those members who were unable to attend missed a great treat.—I am, yours, &c.,

W. H. PRESTWICH.

155, City-road, London, July 13.

NEW RULES OF THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

To the Editors.

GENTLEMEN,—Now that an effort has been made to accomplish real progress in the business of the above Society, it may not be out of place to mention that a draft of certain alterations, modifications, amendments, and additions to the code of rules of the Photographic Society of Great Britain as passed in 1874, have been recently circulated by the order of the Council, the said alterations having in view the more efficient conduct of the Society's affairs. Of course, when a governing body voluntarily initiates much needed reforms without fear of the probable effect upon themselves, the act is of a nature which deserves to be highly commended, and I think all interested will admit that the revised laws are upon the whole very welcome.

The special meeting called for Tuesday, 19th instant, for the consideration by members of the various provisions embodied in the draft, is too near at hand to admit of previous controversy in your columns. May I therefore ask your indulgence in the matter of space to remark upon one or two points which will give time for the members to consider before the time of the meeting, if they have not already done so? The present month is, perhaps, the worst time of the year for securing a large attendance of members, but the same period was chosen before for a similar purpose, with the result of an exceedingly small meeting.

In the new Rule V. it states, "The Council shall appoint two Honorary Secretaries; the Hon. Secs. shall attend the meetings of the Society and Council, and take minutes of the proceedings. They shall conduct the correspondence of the Society, and one of them edit the journal, &c." These gentlemen are to be appointed by the Council from the members of the Council, so that practically a Council of twenty will have to be elected each year instead of eighteen. I should therefore suggest for consideration the advisability, or otherwise, of acquiescing in that plan, instead of the members nominating two Hon. Secretaries to fill these important posts annually, as they are permitted to do in the case of President, Treasurer, four Vice-Presidents, and eighteen Councillors.

Then in Rule X. it states, "Every member of the Society shall be at liberty to nominate one member as President, two as Vice-Presidents, one

as Treasurer, and six as ordinary members of Council," thus limiting a member's nomination to half the number elected of Vice-Presidents, and one-third of the Councillors. He may nominate only ten in all, but twenty-six have to be elected. Surely no great harm could happen if a member actually nominated twenty-six men whom he believed to be capable and willing to do the work.

Another point is that of providing against continuity of office (other than President), by making retiring members ineligible to again serve within a year. As the rule now contemplated stands, all officers (other than Hon. Secretaries not mentioned) retire annually, but are eligible for re-election, therefore one of the three following conditions must happen at every election. (1), A house list nomination of the entire officers much the same as now constituted. (2), An exchange of official posts as heretofore the custom. (3), An entirely new Council, &c., unused to the work.

Neither condition seems desirable. I therefore submit that the old system which required the retirement of a Councillor after three years' service would, if coupled with ineligibility to fill any other office for one year, be successful in breaking the link whereby it becomes possible for any member to be once an officer always an officer, whether the Society's best interests suffer in consequence or not.—I am, yours, &c.,

W. M. ASHMAN.

Answers to Correspondents.

PHOTOGRAPHS REGISTERED:—

A. Rogers, Bacup.—*Jubilee procession.*

F. Hoare, Cirencester.—*Two photographs of Jubilee procession.*

S. S. Crewdson, Ulveston.—*Photograph of Barrow's Monument and stack for Jubilee fire on Had.*

J. Gibson, Penzance.—*Two views of the Bishop Lighthouse, Scilly Islands.*

H. A.—See an article on the subject on page 521 of our volume for last year.

J. S.—We are sorry we do not know the present addresses of the gentlemen named.

ONE IN A FIX.—Bring the lens to our office any forenoon; we can then tell you all about it.

W. INGLIS ROGERS.—We shall be pleased to have the promised article not later than the middle of November.

M. H.—If the negatives are moderately weak, print in diffused light; if excessively strong, sunlight is to be preferred.

J. T.—We regret our inability to indicate the principles by which Dr. Scott was guided in the preparation of his Table of Exposures.

TRIX.—Better put your query to the *Electric Review*, which is an authority on the construction and power of the different batteries of the latest type.

R. Y. L.—Immerse the opalotype in a five per cent. solution of alum for a few minutes, rinse and dry. This will prevent the film from forming the pustules when the washes of colour are applied; but avoid the matt varnish.

A DUBLIN AMATEUR.—Ruby glass is employed because it is more non-actinic than the yellow formerly used. Gelatine plates are more sensitive than collodion, hence the necessity for using a less actinic light in the dark room.

STEPHEN TALLON.—1. If the glass be perfectly waxed there should be no difficulty in removing the films.—2. Asphaltum dissolved in benzol. Use the solution dilute.—3. Albumenise the paper with plain albumen, and sensitise it by floating the back on a five per cent. solution of bichromate of potash.

E. J. HUGHES.—It is impossible to say which of the two is the more rapid plate except by trial. If you write to the maker, however, he will supply the information. If the stopper is so firmly set as to resist the treatment to which you have subjected it, the best plan will be to knock the neck off the bottle and transfer the contents to another. Before doing this you might turn the bottle upside down and allow it to rest in that position for twenty-four hours, and then repeat the treatment with heat. Sometimes, if the bottle contains an alkali and the stopper gets fixed by its action on the glass, this may loosen it when followed by heating.

NORTH LONDON PHOTOGRAPHIC SOCIETY.—Outing on Saturday, the 16th instant, to Chigwell. Train from Liverpool-street at thirty-five minutes past two p.m. to Buckhurst Hill.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, July 20, 1887, will be on *Tuning*. Saturday outing, Chislehurst. Tea at "Bull's Head," Chislehurst. Train from Cannon-street at twenty-five minutes past two.

No. 1420. VOL. XXXIV.—JULY 22, 1887.

OWNERSHIP OF NEGATIVES.

IN a leading article a fortnight since we dealt with the old and often vexed question as to the right to the negative, taken in the ordinary course of business, so far as relates to portrait photography. There may, however, under certain circumstances, be instances when the "custom of trade" as regards portraiture may be somewhat in doubt, or might possibly lead to litigation unless specially guarded against. We allude more particularly to such negatives as are taken, on commission, for special purposes. In such cases, however, it is customary to make some definite agreement or stipulation as to the disposal of the negative at the time the order is given.

A photographer may be called upon to photograph a document or deed for legal purposes, or, possibly, to copy a picture for, say, photogravure, or other mechanical process not worked by himself. In cases of this description, however, it is usual to have a clear understanding as to who shall possess the negative. When this is done, and it always should be, no dispute is likely to arise. But when it is not, and the photographer stands upon his customary right to the negative, it might give rise to litigation, and in the event of this, the result may very much depend upon the mere wording of the bill or invoice. Let us take an example.

A photographer is commissioned to photograph, say, a mansion and supply a number of copies. He attends, takes the negative, supplies the necessary number of duplicates, and sends in his bill in something like the following terms:—To photographing so many views of such and such a place, so much; and so many copies, so much. In this case, to whom does the negative belong? By many it might be assumed, as a definite charge is made for "photographing," that the negative is the property of the customer, but the custom of trade says differently—that it belongs to the photographer, notwithstanding that he has made a definite charge for photographing, and this view has been sustained in a court of law, as will be seen by reference to page 202 of our volume for 1884. The facts of the case were these:—

A photographer sued in the Swansea County Court the defendant for the sum of five pounds eight shillings and sixpence. The claim was in connection with taking certain photographs of a vessel with groups of the officers on board, the amount of the artist's bill being ten pounds eleven shillings and sixpence made up of the following items: Five pounds eight shillings and sixpence was charged for "photographing" the vessel and groups, and five pounds three shillings for extra copies supplied. The defendant paid the latter amount, but declined to pay the remainder unless the negatives were given up to him, hence the action. The defence was that as a charge

was made for executing the negatives they belonged to the defendant. The judge, after hearing the facts of the case, said, "If you order a photograph, unless you make special terms for the purchase of the negative, the photographer is not entitled to give it up." To this the advocate for the defendant replied, "If he asked a man to make something for him, and he afterwards asked for copies and paid for them, they were his. If a photographer charged him for taking a negative did it not belong to him?" The judge said, "No; it is part of the instruments used in the business. It is what a photographer uses in his business to make photographs. Why should he part with the instruments of his trade? A negative may be a secret in his trade, and he does not part with it unless there is a special contract to that effect." In further argument the advocate for the defence remarked, "Suppose I ask a man to make an engine and he charges me for the patterns, do the patterns belong to me or do they not? If he charges me for them they are mine; if he does not charge me for them of course they are not mine." The judge then said, "But here he does not charge for the negative. He charges for his work and for copies, and he makes an estimate accordingly. You want photographs for your friends; it does not matter to you how he makes or produces them. There might be other means to produce what you want; therefore what has this to do with you. He charges you for the expense in producing what you want. As I said before, he estimates the cost of producing, but does not sell the material used in the production. He wants it for other purposes." In the end the verdict was for the photographer for the full amount claimed with costs and advocate's fees. Leave to appeal was given, but the judge added, "I think, however, it will be useless to appeal." We believe the appeal was not persisted in; consequently this decision stands as a precept the same as the one quoted a fortnight back with reference to portrait negatives.

Had the judge in this case not been so fully cognisant, as he evidently was, of the usages of photographers, it is quite possible that the ruling might have been different. Curiously enough the arguments *pro* and *con* adduced in this case are very similar to those brought forward in the recent discussion on the subject of the right to the negative.

Photographers will, however, do well to be careful in the wording of their bills and invoices in cases like the one just referred to, as upon this much may turn in case of litigation. We have seen invoices made out somewhat as follows:—To taking a negative of, say, a mansion and one proof, so much; duplicates, so much, &c. Now although taking a negative and photographing are synonymous terms amongst photographers, they may not always be looked upon as such by laymen, or by

a judge or jury. Here a definite charge has been made for taking the negative and, may be, if the work has been executed at a distance from home, an additional charge is made for travelling expenses. Now in face of such an invoice as this the Court, not being fully informed of the custom amongst photographers, might, on the point of law, decide adversely to the photographer. But if the invoice were in different phraseology, worded, say, like this:—To a photograph of such or such a subject, so much; and so many copies so much in addition. In this case, although the items charged are the same, the wording of the claim is widely different.

In making out their accounts photographers will do well to avoid making a definite charge for "taking a negative," or even "photographing," as that to the uninitiated implies a certain degree of right to the negative, an idea that might be confirmed by a solicitor, if his opinion were invoked, strictly from a legal point of view. As a matter of precaution, the claim should always be made out for the finished work as it is delivered, and not for its execution. We direct attention to this phase of the question as it is always advisable to avoid litigation when possible.

REFERRING to our remarks a few weeks ago upon the use of coal gas, it may be remembered we described a method of getting rid of the residual gas left in the indiarubber tubing commonly employed for attaching the Bunsen or other burners to the main supply pipes. We may now call attention to another method which we have lately seen in use for the same purpose. Amongst photographers generally, whose use of gas for heating is probably confined to the employment of a single Bunsen, we must say we have rarely seen in use the very simple tap of Mr. Fletcher's make described in our article; yet we may again point out it is most simple in arrangement, and so easy to use that a boy could with safety put it to work. All that is needed in the shape of fitting is as follows:—First, turn off the gas at the meter; then ascertain the position of the lead supply pipe, usually embedded in the plaster coating of the wall of the room, pull it forwards for a few inches of its length (which is readily done by chipping away at the plaster), and cut a piece out about half an inch longer than the metallic part of the Fletcher tap. This tap is supplied with a small piece of rubber tubing slipped over each end, and the free ends of these short tubes are slipped on to the two ends of the lead pipe left after cutting the piece out, and the junction is complete. The tap is sent out with also an attached plate bored with holes, for the purpose of being attached by screws to any existing woodwork, or, failing that, to a peg of wood driven into the wall.

MANY people, however, are much afraid with meddling with gas in any manner that suggests a possible advantage of calling in the inevitable man and a boy. For these Mr. Fletcher has devised still another contrivance so simple that it could be attached by a blind man; it can only be used where there is already a gas bracket fixed, but what room is there nowadays without such fitting? This bracket tap is attached to the base of the bracket. The existing bracket arm is unscrewed from its socket, leaving attached to the wall only that portion of the brasswork containing the tap. The Fletcher tap is screwed into the hole from which the brass arm has just been removed, and then into this added arrangement the arm is screwed. The indiarubber tubing for the Bunsen, &c., can be attached in the usual way, and the use of the old illuminating burner is not interfered with in the slightest. This supplementary brasswork has two taps, one to prevent the gas when turned on passing when not required into the illuminating arm, and a second to regulate or stop the supply to the Bunsen. Now by this arrangement the tubes can be freed from gas just as in the method described on a former occasion, thus:—When it is required to put the heating burner out of use, let the illuminating burner first be lighted; next turn off the gas at the old tap—that is, the one belonging to the bracket proper—the result will be that although the gas is turned off, the upper burner will remain

alight for a minute or two, the small flame being supplied by the gas left in the rubber tube, which by reason of its lower gravity escapes by the upper orifice. We have tested this plan ourselves, and can assure our readers that it thoroughly answers. In establishments where rubber tubing of some considerable length is employed, the gain to the sweetness of the atmosphere is no inconsiderable boon.

THE use of gas for all purposes of lighting and illumination is daily increasing, and marvellous already are some of the contrivances devised for utilising these two phases of its power. We have not yet to chronicle the abandonment of electricity for gas, though we are of opinion that this is far from impossible. An impetus to the invention of new forms is given by the Prussian Society for the Promotion of Industry, which has recently offered a gold medal and two hundred and fifty pounds sterling for the best work on light and heat radiation of burning gases. The end of next year is fixed as the time limit for competitors.

THOSE of our readers attending the British Association who are interested in the opposite side of the question—the electric—will no doubt be interested by the lecture of Professor Forbes, F.R.S., who gives as the subject of the Saturday popular lecture, *The Electric Light*.

PHOTOGRAPHERS are indebted to Mr. Bothamley for the very full account of orthochromatic methods given in his paper read before the Convention. It will be observed, *apropos* of the patent question, that some of the colours he describes do not belong to the eosines at all. First on his list is chrysianiline; this does not belong to the eosines. Erythrosine, of course, as we have before described, does so belong, as also does rose Bengal, which is a soda salt of tetraiodochlorfluorescein. We do not believe that the last word by a great deal has been said upon orthochromatic plates. They have a future before them.

WE understand that the number of foreign men of science who have accepted invitations to attend the next meeting of the British Association is unusually large. The list embraces the names of men of the highest eminence in both hemispheres; almost every country in Europe will be represented.

PROFESSOR R. H. THURSTON lately presented to the Washington meeting of mechanical engineers some memoranda on the production of large photographs by the usual blue process from engineers' drawings on tracing paper, and exhibited a print eight feet long and more than a yard in width. The method adopted, due to Professor Cleaves, does not require the use of any plate glass, and there is no practical difficulty in executing a drawing of almost any dimensions—ten feet by thirty feet, for instance. Professor Cleaves's apparatus consists merely of a cylinder of a length exceeding that of the widest drawing to be reproduced, and of a diameter such that the longest tracing to be used can be wrapped around it with sufficient space to spare to give room for the clamps by which it is drawn into place and held. The cylinder is smoothly covered with felt, and the sensitive paper carefully wrapped about it, the tracing to be copied being drawn over the whole and held smoothly in its place by spring clamps, which seize its ends. It is found to be easy to lay the tracing smoothly over the surface, and to draw it into contact so perfectly that the work done by this method is even better and more certain than that produced by the ordinary plate-glass apparatus, even with the air cushion now so successfully used with it. It is stated, too, that with a little care and practice it is absolutely easier to make these prints in the manner described than when glass is employed.

THE PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.

THE following paper was unavoidably left over last week:—

COLOURED CHLORIDE OF SILVER.

By W. H. HARRISON.

FROM time to time, in most civilised countries, and not always in the great gooseberry and sea-serpent season, the daily newspapers announce to their readers the discovery at last of the means of taking photographs

in natural colours; in such cases investigation always proves that the vendors of such photographs are taking them by known methods and afterwards colouring them by hand. These commercial ventures have nothing to do with true heliochromy, the first recorded experiment in which was performed by Seebeck, of Jena, in 1810; the subject was in later years studied and brought to a moderately advanced state of perfection by Becquerel, Poitevin, and Saint-Florent. Sir John Herschel observed some of the phenomena of photography in colours, but did not follow them up, and Niépce de St. Victor—nephew of Niépore Niépce, one of the fathers of the photographic art-science—produced some of the best photographs in natural colours which have yet been seen; for the most part, however, he merely made use of Becquerel's discoveries, and in this matter was shining chiefly by reflected light, as I have recently become aware while reading up the original memoirs in the history of this subject. Silver plates for this class of work have given the best pictorial heliochromic results, those on paper not being so true to nature after the partial fixing of the proofs. A chief difficulty always has been the fixing of these pictures; some of them will resist the action of daylight for a few weeks or months, but those who produced them say that they will fade at last. They are products of scientific and not of commercial interest.

Quite recently Mr. Carey Lea, of Philadelphia, who has been indefatigable in original experimental photographic research, has succeeded in producing red or violet chloride of silver in bulk, and it is possibly the same substance upon which heliochromic results have been obtained by early experimentalists; hence, as the record came under my notice while reading archaic documents for other purposes, I thought it might be well to translate and forward to the present Photographic Convention at Glasgow what Becquerel thought of the coloured chloride of silver upon which he obtained his photographs in natural colours.

In vol. xxii. of the *Annales de Chimie et Physique*, Paris, 1848, Becquerel says:—

"I think that the compound formed on the metallic silver under the action of chlorine, is a special chloride, perhaps a violet subchloride, or a mixture of white chloride and subchloride."

In the *Annales de Chimie et Physique*, vol. xxv., 1849, he says:—

"If freshly precipitated white chloride of silver is taken, well washed in obscurity, then extended upon ground-glass or paper, and a portion of it covered with an opaque screen, while the other part is exposed to a feeble light, when the solar spectrum is afterwards thrown upon the surface, so that half of it falls upon the exposed, and the other half upon the unexposed part, the action of the spectrum upon both can be observed simultaneously. After the lapse of a little time, and with diffused light eliminated, under the blue and violet rays both the chlorised sections are alike coloured violet; from the red almost to the blue no effect is produced upon the white chloride in less than about half an hour, while on the pre-exposed chloride the red rays give a slight rose tint, and the green rays a green tint. If, instead of using well washed chloride, photographic paper with free nitrate of silver is employed, the effects are complicated, and the colours entirely masked. The effects of continuation between the blue and red, which I described several years ago, can then be observed. . . . Among the solutions which destroy the colours of photochromatic images, and which dissolve and decompose chloride and subchloride of silver, and precipitate metallic silver, the most active is liquid ammonia. When a coloured proof of the spectrum is washed with this, the spectrum appears as a greyish band upon the brown ground of the plate. But if this band is examined with attention while the film is still wet, it is seen that the extremity which was red before the washing has now a slight green tint, whilst the previously violet extremity is now blue; these tints are complementary to the first; when the plate dries the effect disappears."

Mr. Carey Lea seems to me to have been making chloride of silver reduced in small part to a coloured mixture which curiously resists the solvent action of nitric acid; the heliochromic films are likewise partially reduced, but by exposure to diffused light or prolonged heat before they are used to photograph colours. When, however, one has haloid salts decomposed to such an extent as to be coloured red or violet, I do not yet see what that has to do with the nature of the latent image, in which there is no evidence either to eyesight or to chemical tests that such coloured salts have been formed. That an image should develop where a sensitive plate has been marked with hypophosphite of soda, perhaps merely means that the developer has a more intense action there, as from its composition one would expect hypophosphite of soda to be a developer; it is not so, however, at normal temperatures. That a weak solution of it should have a retarding influence may be regarded as a curious unexplained fact. Supposing that the method had been continued until the water used to mark the film contained no hypophosphite of soda at all, and supposing a developer were then applied to the film before it was absolutely dry, would not with most plates the silver deposit upon the damp parts then be lighter than upon the rest of the plate? Mr. Carey Lea's utterances about the red haloid salts do not seem to be yet finished, and these critical comments are made chiefly with a desire for additional information. I am very glad to see his contributions once more in photographic literature.

As in most original discoveries, at first it is impossible to see the future practical value of Mr. Carey Lea's interesting revelations, nor does the true man of science care for future practical issues when laying bare to the world a new truth about the phenomena of nature. In this instance chemical methods of producing heliochromic chloride of silver in bulk seem to have been discovered, consequently if Mr. Carey Lea would tell us how attempted pictures in natural colours produced upon it compare

in point of accurate rendering of hues with those obtained by Edmond Becquerel, Poitevin, and Saint-Florent, an interesting point would be cleared up. The discoverer is able to select the sample of red chloride which gives the best results, because of his antecedent experience; the reader who wishes to try for himself does not know by which of the numerous methods of preparing the new chloride he is likely to get the best promise of good heliochromic results.

This coloured chloride will probably help to give a true theory of full printing upon ordinary albumenised paper, but where is its link of connection with the nature of the latent image? How do its properties explain the experiments of Dr. Janssen, of Paris, who obtained three or four reversals of the invisible image successively upon the same film? How do its properties explain Mr. Carey Lea's own noted experiment of the past, of the image upon pure iodide of silver dying out again and again during a rest in darkness, and afterwards leaving the plate ready each time for a fresh impression? The two last questions I have several times put straight to the advocates of the chemical hypothesis of the latent image, and have never been able to obtain a straight answer.

We hear much talk about suboxide and subchloride of silver, but nobody has yet been able to produce a sample of either which chemists as a body will admit to be such. Dr. Hodgkinson does not believe that his production is subchloride of silver, but a salt containing oxygen; possibly it is the same chloride that Mr. Lea has manufactured.

There will perhaps be some difficulty in getting behind the dynamic hypothesis of the latent image first launched upon the world by the late Mr. Mungo Ponton and myself, which is that the invisible picture is due to modifications of the relative motions of the atom of chlorine and the atom of silver, so that at one portion of the new vibratory swing set up by light their attractions are so weakened that the chlorine can be seized by the developer. This hypothesis readily accounts for the re-sensitising in darkness of an exposed film of pure iodide of silver, and is the only hypothesis which as yet has in any way been used to explain Dr. Janssen's experiment. It also explains why some parts of the spectrum act more than others upon sensitive salts.

On bromide of silver suspended in gelatine, the latent image may last for months, or in some cases perhaps for years, but analogies of the same nature may be found in the realm of physics.

Some samples of powdered fluor spar temporarily phosphoresce beautifully upon a hot shovel in the dark; put the same powder when cool a second time upon the shovel, and it will not phosphoresce again unless meanwhile it have been sufficiently exposed to light. Here we have the results of luminous energy stored up by some means in powdered fluor spar, without any evidence of the intervention of chemical decomposition. Professor Dewar has stored up the phosphorescent energy of luminous paint spread upon a glass plate, by keeping the plate at an excessively low temperature for days or weeks; on taking it from its frigid receptacle and breathing upon it, once more it begins to shine in the dark until its original normal amount of phosphorescent energy is exhausted. He has facilities at the Royal Institution for producing the extremely low temperature necessary, as there are appliances on the premises by which even oxygen can be liquefied by intense cold and pressure. An analogy upon a large scale may now be given. Suppose the earth to be an atom of chlorine and the sun an atom of silver, and their present relations in the matter of distance to be normal. At the present time the elliptical orbit of the earth is so nearly circular, that if it were to be drawn to the reduced scale of a yard in diameter upon the wall, it would be necessary to measure it for the observer to make sure that it was not a true circle. Because of the perturbations set up by the planets, it at times assumes a very elliptical form, so as to give the earth a short, blazing summer and a very long, cold winter; indeed, this furnishes the foundation for the hypothesis most popular with astronomers as to the cause of the glacial epochs. It takes many thousands of years for the orbit to change from its most circular to its most elliptical form, and in the latter case, when the earth is farthest from the sun, evidently its attraction by the sun is weakest, and it is more liable than at any other time to be separated from the sun, should any stronger attracting body come near enough. Here then, on a large scale, we have something suggesting that upon a small scale modifications set up by a disturbing force in the relative motions of two adjacent particles of matter may possibly last for an exceedingly long time. In intermolecular motions there may sometimes be small tendency when a change say, in merely the plane of atomic vibrations is set up, for the particles to return quickly to their normal positions.

The established discoveries of modern science in relation to molecular physics cannot be excluded from photography, and as atomic motions invariably underlie and precede chemical changes, they must be taken into account in any chemical, physical, or other hypothesis of the production of the latent image by light.

THE EXHIBITION DEPARTMENT.*

George Mason & Co.'s exhibits, which were the most extensive in the rooms, embraced many new and useful pieces of apparatus.

One article that gained general attention and approval was a beautifully finished camera arranged to take plates 24 x 24 inches and downwards, with appliances for drawing out and swinging, also for

* Continued from page 445.

carrying the various sizes of plates, that was really the perfection of simplicity. This camera is specially constructed for studio work, and draws to about six feet. In these days, when large direct pictures are being shown in every exhibition, and a demand for them seems gradually growing, this camera will be hailed by all workers in this field as a valuable introduction. Other improved forms of studio cameras for smaller sizes of work were exhibited, and all were constructed for the best effects being produced by the simplest means.

We have before noted Mason & Co.'s new automatic stand, which gained such praise at the Derby Convention. It was shown at this exhibition and fully appreciated.

The Mason & Co.'s "fixing" and "alum" grooved troughs were also on view. The value of these troughs is so widely known to the profession now it is needless here to descant on their virtues. England's print washer and washing machine, that was familiar to the trade some ten years ago, has been again introduced by this firm, and we think wisely, for it is a good machine, and it will be found of great value to amateurs, who have often but a few prints to wash at a time, as we see Mason & Co. have introduced quite small sizes to suit their requirements. We saw in all the various sizes the zinc vignettes we had occasion to notice some time ago. They are very nicely finished, and in many cases must be preferable to glass.

Dark-room lanterns of every style and pattern conceivable were shown by them, in cloth and in glass, for candle, oil, or gas—something to suit everybody. Tourists' cameras of every description—their usual make and finish, with which the profession are quite familiar, and which have always been in the front rank of photographic manufacture. Roller slides (various forms) were shown on their table.

In these days of developed prints we noted a special tray made of *papier maché*—not the usual jointed corner tray, but one pressed out in one piece; we saw them there from the smallest size up to 34 × 27 inches. This, we think, has been a felt want for a long time, and will be welcomed by many. Ebonite trays and glass developing trays were also shown.

Some cut-out show mounts with hand-painted artistic patterns were exhibited and much admired.

We also visited the Accessory and Furniture Warehouse belonging to George Mason & Co., and situated in Hope-street. Being crowded out with stock in their own premises, 180 to 186, Sauchiehall-street, they have opened this Hope-street warehouse for the showing of accessories only. Such a varied collection of tables, chairs, stairways, rocks, vases, rustic sets, stiles, tree stumps, backgrounds, grass mats, carpets, curtains, &c., are not to be found in any photographic warehouse within our knowledge, and require to be seen to be believed. The newest, and best, and latest accessories are to be found within its walls.

We have but to repeat what we have said on a former occasion—it is always a pleasure for us to wander through George Mason & Co.'s warehouses, for they are ever to the front in securing novelties, and something new is always cropping up at every turn.

CONVENTION JOTTINGS.—III.

(From our Special Correspondent.)

WHEN the business of Tuesday was over it was a sight to see the company of photographers from all parts congregated in Cranston's "Waverley" smoking room, gathered into little knots, each party thrashing out their own pet subject, formula, or process, in the best of humours, and all going merry as a marriage bell.

On two former occasions has this same room been in much the same crowded condition with professional photographers. The first time was when Lambert came round selling and demonstrating his carbon process, and the other was when the British Association held their meeting in Glasgow. This Convention meeting, however, far surpassed these, both for numbers and as a representative gathering. As I sat in this room, listening to the hum of many voices, the air was filled with the tag end of speeches, in which roller slides, films, plates, paper, and gelatine, got sadly jumbled up, whilst some of the weary ones were snoozing away quite comfortably on the cushions in the corners of the room, unconscious of the noise—sufficient unto them had been the pleasures of the day, and they were making ready for the morrow.

There were two trips on Wednesday, the 6th—one under the conductorship of Mr. John Stuart, up Loch Lomond to Tarbet, at this point crossing the hill to Loch Long, returning home by the Clyde. This party had a very enjoyable day, the weather being all that could be desired and the scenery very charming. One of the members had a very innocent practical joke played upon him during this trip. The mountain air being too strong for him, he fell asleep on a seat on deck, when a wag of a photographer exposed a plate upon him, and all unconsciously the sleeping one saw himself projected on the screen in the evening, much to his own astonishment and the innocent mirth of his fellow travellers. The influx of the camera men at the head of Loch Long caused a considerable stir at the hotel, where dinner was prepared for them with all speed. When the dining room was filled five of the party unaccommodated retired to another room, where they enjoyed themselves right well up to the sweets appearing, which were served in so small a quantity that one facetious fellow took out a magnifying glass, and applying it to the dish tried to enlarge the contents, whilst another handed him a saltspoon to divide it, so that it might not be served out in too large quantities. All returned home highly delighted with their day's outing.

The other trip was by the steamer "Vanguard," which had been specially engaged and arranged for those photographers who desired a day's instantaneous work—the Largs Regatta being the scene of operations, and the ostensible business of the trip to follow the graceful white wings and catch them on our plates as they speed through the bright rippling waters. Luck favoured us, for amongst the yachts to run were the "Thistle" and the "Irex"—the renown of the former of these being now world-wide. You can understand that such a chance as this to get pictures of her was hailed with great glee by all the company, amongst whom were many notable men.

This trip was under the conductorship of Mr. George Mason, and Mr. T. N. Armstrong kindly undertook to manage the arrangements for sailing, slowing, and stopping at the various points which would give the friends the best chances for exposures—and this part of the work was done to perfection. It may be stated, without fear of contradiction, that all got their fill of yacht-taking during this trip, for no less than 318 exposures were made, the results being yet unknown.

After the races were over we had a little leisure, when groups of the company were taken by Mr. A. Seaman, of Chesterfield, and Mr. Russell, of Kirkwall.

Then an impromptu concert was held on deck, where a very happy hour was spent by the collected visitors, when the following gentlemen favoured the company with songs, &c.:—Mr. Pringle, Mr. Crooke, Mr. Armstrong, Mr. Fry, Mr. Mason, Mr. Henderson, of Perth, Mr. Browne, of Paisley, and others.

During the day Mr. Turner, of Gourock—an enthusiastic amateur, who, like M'Pherson at the Flood, was cruising about in a boat of his own—took two negatives of the "Vanguard" and her photographic cargo.

At the evening meeting a telegram was received by cable from Mr. Charles Gentile, of Chicago, as representing the Photographers' Association of America, wishing the United Kingdom Convention all the success that could be desired, which was received with acclamation.

ON THINGS IN GENERAL.

JUNE and Jubilee, July and Convention, are the catchwords of the present and the past month, and equally fateful to photographers. I have been trying to calculate how many Jubilee negatives are likely to have been taken on the famous day, but am lost in a maze. There are quite a number published; but most of what I have seen are very mediocre sort of affairs altogether. One reads on the outside of the boxes of plates one purchases "thirty," "forty," "sixty," "times the rapidity of wet," and on others, "special instantaneous," and so on *ad nauseam*, yet the Jubilee results, with such asserted rapidity before us, do not, taken as a whole, show anything very greatly exceeding the results achieved on glass thirty years ago, or on silver plates years before that. How can this be satisfactorily explained? Very few makers admit their ordinary plates to be less rapid than "thirty

times wet;" yet there are few professionals whose average exposures are below, say, three seconds, and this with a thirty times plate would represent an average in former times of ninety seconds, which is absurd. Let us work the question the other way. I do not think I can be wrong in giving thirty seconds as a very high average of wet plate work in the days when were produced the negatives whose abandoned beauties M. Davanne so deplores; nor is three seconds, I am sure, by any means an unfavourable estimate as regards the rapidity of the dry plate of the period. That gives "ten times," rather than "thirty," or the apocryphal "sixty," that characterises so many plate box labels at present. It has been asserted that for very quick work gelatino-bromide does not exhibit so great an increase of rapidity over collodion as it does with more ordinary exposures. I will not pretend to offer a reply to such a question; but the fact remains, as I started by saying, the Jubilee pictures of any merit that have come under my notice do not exhibit traces of extremely rapid exposures.

Do these pictures sell, I wonder? or does the average photographer take such subjects as a matter of course because they are curiosities and part of the things he is supposed to take as a matter of course?

It is no doubt exceedingly probable that photographic representations of incidents connected with the present Jubilee celebrations will fetch a large price on the next Jubilee day; but the photographer of these times does not generally work for the benefit of posterity. I have an idea, though, that whenever a crowd of people is photographed successfully, nineteen out of twenty of those who are plainly recognisable in that crowd are seized with an irresistible desire to possess a copy. A photographer of my acquaintance who was smitten with the general photographic fever is a disappointed man. He got an excellent photograph of an immense crowd, but he says no one will buy—there is no expression in any of the figures; the truth being that nothing but hats and sunshades are visible, and there really, when one comes to think of it, is not a wealth of expression in a hat.

Passing on to Convention matters, I have to say that if the Jubilee did not prove to be of much benefit to photographers, there are very few who would not be benefited by a perusal of the papers read at the Convention—papers by some of the best men of the day. Whatever was gleaned by hearing them read, still more may be gained by reading them quietly through, as one can do at one's own fireside, thanks to THE BRITISH JOURNAL OF PHOTOGRAPHY.

Of course, among such a concourse of good things, there must be here a target for a good-natured shot; but I am speaking of the papers as a whole, and I recommend all my readers who have not already done so, to give themselves a good time by a perusal of the Convention utterances.

I notice a humorous paper on *Metrical Measurements*, the writer of which follows a common lead in advocating the use of a decimal system of weights and measurements. My opinion is that the chief advantage of the decimal system is that it is likely to be universal, and so confusion will be avoided; but that it is convenient for general use I distinctly deny, and I believe it to be a fact that in the countries of its legal adoption it is by no means universally employed. By-the-by, what does the writer mean by speaking of the time when, "to all intents and purposes we shall become a bit of Europe?" I thought we were a part of Europe at the present moment.

The genial writer of the paper on *Elementary Photo-micrography* can be followed in his remarks with pleasure, and the account of his experiences in the work will doubtless be of value to any one seized with the mania, and this is ever a very powerfully acting mania when once it has taken full possession. When he says the "finest line that was ever drawn by mortal man is a cable in comparison to the lines that may be produced by photography," he well illustrates the fairy-like beauty of the results; but the word "drawn" must, of course, be understood to mean drawn with a pencil.

In *Home Portraiture* there are some capital remarks, and I would draw especial attention to the paragraphs in quotation marks in regard to the relative positions of body, head, and eye, in portraiture. A very important, and little regarded, subject is there treated succinctly and usefully. One commonly experienced difficulty is alluded to in a way which will give the portrait photographer not conversant with the canons of art a useful hint or two in discussing matters with his

sitters. I allude to the very commonly expressed desire that the "face should be looking at you," that is to say, that the eyes should be turned to the spectator. No photographer would think of putting body, head, and eyes, directly facing the camera, and Mr. Hough's words explain the conditions under which only the required arrangement may be carried out. With head and figure well turned from the camera and the eyes looking into the camera ("three-quarter face, please, and the eyes looking at you"), the effect will be objectionable; but by keeping the body in the same position and bringing the head nearly, but not quite, to full face, the eyes may look into the lens with the most pleasing result. In the former case he says you have an effect of "shyness, coquetry, or suspicion." The old miniature painter from whom years ago I gained many hints in portraiture, used to call the effect a leer, and I think that exactly defines it.

The writer of *Photography from One Point of View*, in one line sums up the one distinguishing characteristic separating the good from the bad, the artistic worker from the mere workman. He says we may in a moment "secure any beautiful effect if we only know how to look for it, and see it when it presents itself." Ah, there's the rub! What man can take a picture in the true sense of the word if he does not know one when he sees it? He is a poor, contemptible fellow who does not work up to a standard of some sort. A truly artistic standard is not and cannot be erected in the mind of every one who owns a camera lens. Let those whose culture is sufficient be thankful that such is the case; were it otherwise, photography as a profession would soon be played out.

FREE LANCE.

COLOURING AS APPLIED TO PHOTOGRAPHY.*

ALTHOUGH the general idea before us is to treat of the many and various ways of applying colour to photographs, there is no reason why, in discussing *portraiture*, the photographer should be considered less than the colourist or amateur. Indeed, we should all try to advance hand in hand, as in the end it is our *united* work that must stand the test of criticism, as well as give satisfaction to our clients.

It may be said that while I jot down a few remarks on portraiture generally, I am not strictly within my rights as defined by the title of these papers; nevertheless, they may be found useful, inasmuch as they will remind, if not instruct, as to the general principles which should guide us in everyday studio practice.

In the production of *cartes-de-visite*, cabinet three-quarters and full lengths, and, indeed, in all sizes where the figure is shown, there is considerable tax upon the art knowledge of the photographer before he will secure a successful picture. There is much more scope in these phases of photography to exhibit the operator's skill and knowledge as regards arrangement and composition than in any other. By this I do not mean to convey, however, that there is little or no knowledge required to pose a head and shoulders satisfactorily. On the contrary, there is a very great deal of artistic knowledge and feeling required to secure that turn of the head which will give it importance as well as endow it with intellectual expression. I may say I know several very successful photographers who make most excellent pictures when engaged on subjects showing the entire figure; they show consummate skill in the lighting, also in the adjustment and general arrangement of the draperies, yet when they take a head and shoulders their pictures are ordinary to a degree. They are photographs simply, without that artistic touch and feeling which alone can entitle them to be called portraits. It would not be fair to mention names here, but there are two or three photographers in London upon whose work (I mean as regards head and shoulders more especially) I have always dwelt with great pleasure. The artistic feeling, possessed to no small degree by the operator, has been visibly secured upon the faces of their subjects.

At the outset it may be just as well to consider what is and what is not a *picture*. The mere reproduction of an object or the exact delineation of a face, although granted it be a likeness, will most certainly not constitute a picture. No, there is much more than this necessary. In order to produce a really good portrait, and at the same time endow it with those qualities which alone can make it a pleasing picture, the subject being treated should be represented under such

* Continued from page 407.

conditions as regards position, general arrangement, light and shade, appropriateness of surroundings and accessories, &c., as will unfailingly indicate character, endow it with true intellectual expression, and yet at the same time lend themselves to the general pictorial effect.

The photographer must always labour under a very serious disadvantage, inasmuch as he can never, personally, have absolute control over his models, either as regards their facial expressions or, to a great extent, the varying effects of light and shade, which he would wish to secure in his models, this notwithstanding he may possess considerable taste and general knowledge of art. However, much can be done towards the production of a picture that will not only be such but also be a good portrait. The operator can always, at least, select his positions, to a very great extent control the general influences of light and shade, and so secure the most pleasing and characteristic lines and features of his models; by the judicious and thoughtful selection of his accessories, and the artistic arrangement of same, he is enabled to do away with harsh lines that otherwise might exist and so mar the beauty of his work. With the liberal use of accessories, too, which nowadays seem quite customary in photographic portraiture, tone or colour can be given to portions of a picture where same may be desirable; but care should be taken, all the same, that all such aids should tend to produce artistic simplicity, general harmony, and a feeling of breadth in the finished picture.

In composing a picture, more especially when the figure is to be shown full length, one of our most important considerations is the selection of a position. Character, as well as general pictorial effect, depend greatly upon the success of our choice in this matter. There is, still further, another point to consider, even when the position of the model is successfully fixed upon, and that is the position it shall hold in the picture itself. This may not appear a very important point at the first glance, but a very little consideration will show that it may be of vital importance. The figure should I may almost say *never* be placed in the middle of the picture, that is to say, equidistant from each side; there is no position more formal or destructive to pictorial effect than such a one. As a general all round rule, it may be accepted that more space should be in front of the figure than behind it. Of course this disposition may be rendered inadvisable owing to some peculiarity in the arrangement of the surroundings. This one's own artistic feeling will easily point out. If a lifelike appearance should be secured for a figure in a picture, and the semblance of motion almost visible, it is more pleasant to feel that the model is walking *into* the picture than retiring out of it. This is one case where the slight advantage of space before the figure will prove an advantage. The same idea will be found applicable, but for another reason, as regards the position of the figure being equidistant from the top and bottom of the picture. I think the latter is more important even than the former, and much more destructive of truth and pictorial effect not properly considered.

By the distance from the top and bottom of a picture can we alone fix an idea as to the height of the figure represented. The nearer the head is to the top of the picture, the taller the figure will appear to be; the lower the head is, the shorter will be the appearance of the subject. If you take, for example, an officer in the Life Guards, and you want to give him the appearance of height (and there are many, by-the-by, who require it), select your accessories such as pedestal, &c., rather low (some have accessories expressly for the purpose), and cut the picture so as to place the head near the top of the mount, and your effect is at once gained. As I said before, full length first, then three-quarter length figures, demand most attention from this point. In larger portraits, especially head and shoulders, it is not so necessary a consideration, but should, nevertheless, *always* receive our best attention. Thus a bust, say, in profile or even three-quarter face, should have more space before than behind, while a similar figure presenting a full face may, without being in the least inartistic, be placed in a position equidistant from both sides.

The various positions in which the human figure may be placed may almost be considered limitless, but every one should aim at securing grace, ease, and character—a result seldom arrived at the first time of asking. An operator wishing to secure these qualities in his pictures should always have an object or purpose reflected in the position he selects. This does not necessitate that the sitter or model should be absolutely engaged in any particular action or occupation,

but that due attention be given that the expression of the consciousness of being photographed, or that of complete vacancy, be not depicted upon the features of the same.

In ladies' portraits it should be easy to give action or intention to one's models—reading a letter, arranging flowers, gazing upon a picture, &c., may all be adopted at the operator's will. In portraits of gentlemen these occupations would not be so happy. However, others are at our disposal, and even the very conventional "book in one hand" may be adopted, but not necessarily in the conventional manner, but with expression and purpose.

Some approve of entire repose; I have nothing to say against the same when it is what I may be allowed to call an "intellectual repose." In this, however, there is a danger of producing the appearance of vacuity, which of course would mean ruin to a portrait both as a likeness and as a picture. Straight lines and angular positions should be carefully avoided in all cases; there is much more of the ugly than the beautiful about them. There is a great deal of skill required in this regard, and I have known some sitters who have defied some of the very best operators to secure them in graceful positions, but, thank Providence, they are not very numerous. The human figure in a perfectly upright position is not at its *best*, although perhaps at its *highest*. It lacks grace in a man, and is absolutely awkward and almost offensive in a lady. The figure may lean slightly against any article of furniture, such as a high-backed chair or screen, or in any manner so as to induce a slight inclination, and thus secure curved and flowing lines both for the figure and the drapery.

If the figure be standing, a more perfect feeling of ease and balance is secured by making the weight of the body rest upon one foot rather than upon both. It is very difficult indeed to secure ease, not to say elegance, and at the same time rest the figure equally upon both feet. All action, or suggested action, that may be sought for in a model must never be attained at the expense of ease and grace. In the suggestion of an overstrained muscle or a dislocated limb the most skilful artist will fail to depict a grace or secure a pictorial effect.

When we come to a question of composition it will be well to keep before us the axiom that the most perfect and beautiful effect to be gained is simplicity. Over elaboration or complexity is most objectionable in portraiture at any time, but in photographic portraiture it is more strikingly so. It is most important that a perfect balance, both as regards lines, and light, and shade, should be secured. In the study of the works by Sir Joshua Reynolds, or any of our famous old portrait painters, the student will be struck by the graceful tendency of all the lines as well as the simplicity and unpretentiousness of the colouring. Yet what beauty! You never find all the lines in a picture running in one direction, the effect would be harsh; nor do you find a picture badly balanced by having all the masses accumulated in one corner of the picture, leaving the rest bare and unsightly. This is a more important consideration perhaps for the photographer even than the painter, for the latter can, by the aid of colour, create a balance where the "one tonedness" of the photograph would only accentuate the faultiness of such a composition. REDMOND BARNETT.

(To be continued.)

ACCESSORIES OF THE LANTERN.

CHAPTER X.—JET FITTINGS.

THE usual shape of the lime is a cylinder, about an inch and a half long and three-quarters of an inch in diameter. This cylinder is perforated by a hole one-eighth inch wide in the line of the axis, which allows it to be supported upon a brass or iron pin placed in front of the jet nozzle. The distance between the point of the nipple and the surface of the lime may be an eighth of an inch with mixed gas jets, the area of incandescence being a circle varying from a quarter to five-eighths of an inch in diameter, according to the force of the gas supply.

Jets of large aperture cause a pitting of the lime similar that caused by small apertures; the pits or depressions are wider in the former case, and it is sufficient—with a hard lime and a moderate gas pressure—to partly turn the lime by hand once in ten minutes. If the lime remains stationary for a longer period than this, a deep depression will be formed and the flame may be altered in direction in

such a way as to put the condensers in danger of being cracked by the heat; besides this, the light is not so good as when a fresh surface of the lime is presented to the action of the burning gases.

The employment of clockwork to cause a slow revolution of the lime is a very old contrivance, dating from the first introduction of the limelight. There are special clockwork movements supplied by opticians for use in lanterns, which not only cause the lime to revolve but also produce a motion in a vertical direction, so that the flame acts on a spiral or corkscrew path round the lime. I have had some experience with these movements, having applied a set of three American clocks to a triple lantern. The clocks had loud-ticking watch escapements, and when all three were at their appointed work—turning the limes under the influence of strong mainsprings—the effect was such as to induce those members of the audience who were nearest to the instrument to glance at it in wonder, and remark that it seemed to be alive, especially if a jet happened to chime in with the music by hissing or roaring a little, owing to a high pressure of gas.

The clocks were accessories that required oiling occasionally besides winding up, and the top one of the three, owing to the heat, was apt to get out of sorts and required careful supervision. Doubtless with a single lantern the stopping of a clock would be noticed immediately by the cessation of the ticking noise, but with a triple, the resting of one seemed to induce the others to tick with increased energy, and so the total sonorosity was the same as before. The clocks had another fault—they failed to sound an alarm if a lime happened to fall to pieces, the result being that a lime pin occasionally was melted down to a very short stature. This compelled the operator, in order to keep his mind at ease, to glance every five minutes at the machinery inside the lantern, and the notion eventually occurred to him that the clocks were false friends, as it would be just as easy for him to turn the limes by hand once in ten minutes, as to keep the necessary watch on the mechanism. So the clocks received notice to quit: they gave up their posts, and have never been recalled since.

There are two ways of turning the lime without opening the door of the lantern; one is to have a pair of small cogwheels, with bevelled toothed edges, working at right angles to each other, the other method is to connect the upright lime pin by a coil of wire with a horizontal pin having a brass button at the end to turn it by. Each of these plans answers its purpose well, provided the teeth of the cogwheels are kept free from grit, and the coil of wire is not softened by the heat of a jet in a lower position, as in a biunial. The up and down motion is usually given by putting a screw thread on the lime pin, and a corresponding thread on the small brass disc that supports the lime. This is a very defective method, as the lime dust gets into the threads of the screw and causes the action to be very stiff. It would be better to have the up and down motion entirely distinct from the revolving action; the former is not absolutely necessary, as if the flame strikes the lime at the lower portion it is easy, by turning the lime upside down on the pin, to ensure the upper portion being also acted upon. Simplicity is a great virtue in lantern apparatus; on this account I prefer to have no cogwheels and wire helices in a biunial, as the opening of a door does not send the flood of light into the room which occurs with a single lantern. The lime pin may be a brass wire one-eighth inch thick and two and a half inches long, at the bottom of this is fixed a disc one inch diameter, with a rough milled or toothed edge, which enables it to be turned by a touch of the finger. Another brass disc, half an inch wide, is soldered on the pin one inch from the top; the lime rests upon this disc. The pin is held loosely in a brass tube one inch long and three-sixteenths inch bore: this tube encircles the pin between the discs, and is itself supported by a curved arm hard soldered to it, and clamped to the jet tubes.* This lime support cannot well get out of order, and I can recommend it as simple and efficient.

The tin trays which formerly were always employed to support the jets are now less frequently made; it is a much better way to have an upright iron rod, three-eighths inch diameter, permanently fixed at the back of the lantern, to which the jets are clamped by strong thumb-screws. This rod should be firmly fixed at both ends in such a way that no twisting motion is possible; a bearing in the middle is unnecessary in a biunial, as it is an advantage, after an exhibition, to be able

* The lime pin has a little play in a vertical direction, and is retained at any height by a spring which presses it against the sides of the encircling tube.

to slacken the thumb-screws, and allow both jets to slide down the rod to the bottom of the lantern, leaving the interior empty and available for packing away slides, &c. This can be done without having to pull the rubber tubes off the jets, if the former are properly arranged.

With a mixed gas jet, it is immaterial which tap is used for oxygen; it is well, however, to have a uniform system for use with all jets. One particular side, such as the right-hand one, should be devoted to oxygen, and the other side, or the left-hand stopcocks, to coal gas. This will prevent hesitation when a readjustment of the taps is necessary.

Some operators are inclined to give the preference to a single lantern, rather than use a biunial. With such methods of changing the pictures as are adopted in lanterns now procurable from opticians by which an instantaneous change takes place without apparent motion of the image on the screen, it is easy to understand this choice. A biunial is the best instrument for general lecture exhibitions, as there are very few effects that cannot be shown by it. A triple lantern is more ornamental, perhaps, than a double, but this does not compensate for the extra weight, complexity, and expense; the third lantern is often not used at all in exhibitions. The chief fault of single lanterns has hitherto been their inability to show the dioramic effects which require two pictures to coalesce and form one view, and also to change ordinary views in a pleasing manner. The latter defect is now practically overcome, and by using special slides it is quite possible to show most of the usual dioramic changes with a single lantern, such as day and night effects with windows, &c., lighted up; swans swimming on the water, with bending necks, as in the "mill" effect; the flash of forked lightning; the rainbow, and certain others. The "rolling curtain" method of changing slides can be as perfectly and easily accomplished with a single as with a double lantern. There is a very effective way of showing statuary views by first projecting on the screen a gorgeously decorated curtain, which appears to roll up and disclose the white marble behind—this effect lies within the domain of the single lantern, which I expect will be the "lantern of the future" for general use. ALBERT WM. SCOTT.

NOTES ON PHOTOGRAPHY AT SAN FRANCISCO.

THE thing amongst things photographic that I have seen here that has interested me perhaps more than others, is a series of large Daguerreotypes of very good quality showing the bay in 1851. These Daguerreotypes hang in the rooms of the Amateur Photographic Association of San Francisco, and are interesting because they illustrate a bit of history. In this year (1851) the "gold fever" was at its height. In all parts of the world people in all positions of life were casting aside their employments, leaving their homes, their friends, and all ties, and were rushing, like beings possessed, to the newly-discovered gold fields. Ships arrived at San Francisco from all quarters of the globe, and immediately they set anchor in the bay men deserted. Not a sailor or hand on them but what caught the fatal fever, and sped inland to the diggings. A man could not be hired for twenty dollars a-day, and the ships had to be left to rot where they first dropped anchor. The Daguerreotypes referred to showed the hulks lying on the waters in various stages of disintegration. On the hulk of one ship is painted up in large letters, "Store," the owner, or his representatives, having evidently become resigned to the idea of letting her rest where she was.

It appears that the part of the bay where the greatest crowd of ships show in the old photograph has since been reclaimed—has been filled in, that is, and has been built over. Recently, some rebuilding was going on, and the excavations came right on to one of the old hulks. They were never removed, but the earth was filled in around them: they were literally buried.

Rough times those of the gold fever must have been. I imagine that but a small percentage of those who made so wildly for the diggings ever came back again.

Talking of rough times reminds me that I have seen, since I have been in America, two photographs of "lynchings," or rather of the hanging bodies of the victims after the lynchings were over. Repulsive enough looking pictures they are. In one case the body is seen hanging from a set of shear-legs, apparently erected for the purpose of the execution; in the other it hangs from the cross-bar of a telegraph pole. In each case there is a crowd of men underneath who have an expression of cheerful satisfaction—on account of their own superior virtue, doubtless.

It was my impression that this sort of thing had died out, even in

the extreme West; but it appears it has by no means done so. I took up a local newspaper a few days ago, and saw in it that an attempt was being made to seize two negroes out of one of the state prisons to lynch them, and that if the attempt were continued "bloodshed would certainly ensue." The object of the lynchings is not very evident, for it appears always to be some criminal who would be hanged legally in any case who is selected. The excuse is that it is done to prevent a miscarriage of justice; but it seems to me that more of the brutal element, which is always ready to rise if it be not kept under, is in the thing than anything else.

In the gallery of Taber, an eminent photographer here, I saw a series of photographs taken from a balloon, which struck me as the best thing of the kind that I had seen. I send prints of them, in hopes that they may be considered good enough—some or all of them—to be reproduced. The following is a brief account of the trip given to me by E. H. Husher, who made the ascent and the exposures.

The ascent was made on the 15th April at 10.50 a.m., being organized by the *Daily Examiner* newspaper. In the balloon were a representative of that newspaper, a professional aeronaut, Professor Van Tassell, and the photographer already mentioned. The greatest elevation reached was 2000 feet, and there appears to have been some difficulty experienced in preventing the balloon from drifting out to sea.

The camera used was 10 x 8 size, and it was fixed on a swivel arrangement over the edge of the car, which enabled it to be directed at any angle with the perpendicular. Twelve plates of American make were taken, a No. 3 Euryscope lens was used—precise focus not known to me, but long for a 10 x 8 plate—and the exposures were made by the aid of a rapid double action shutter.

From the twelve plates six good negatives resulted. Husher noted what has, I believe, been observed by all who have made attempt at balloon photography, that there is great difficulty in getting contrast in the negative. This is due probably to lack of any deep shadows (the under sides of all objects being of course hid from view, and every point seen being illuminated at least by the whole sky) and also to somewhat of land mist.

On the fact of the difficulty in getting contrast, the *Examiner* representative, in his account of the trip, enunciates some truly wonderful theories as to colours and paintings, heading his remarks, *Important Discovery—The Application of the Theory and Proof of the Theory*. Husher, however, noted that, although very deep shadows nowhere existed, the contrast of colour appeared particularly vivid, and he anticipates that by the use of orthochromatic plates, which register a greater range of colour than ordinary, he will be able, when he makes his second attempt, which will be soon, to get results still better than he has. This appears likely, the whole of a balloon view corresponding somewhat to the distance in a landscape, which distance, as is evident from the result of recent experiments, is better rendered by orthochromatic than by ordinary plates.

Some difficulty was experienced in landing, Husher contriving to get out of the balloon on the top of a tree with his plates unbroken, with the natural result that the balloon, with its two other occupants, bounded into the air again, and only landed for the second time at a considerable distance.

W. K. BURTON.

HOW TO PREPARE GELATINE "POSITIVE" DRY PLATES.

II.

RECENTLY it has been advocated that a film rich in silver salts is necessary to give the best result on the modern positive. This is contrary to my experience. I have tried various proportions of salts, from the maximum amount used for negative plates, downwards to about ten grains per ounce, which undoubtedly gives the most uniform and brilliant result. To support this conclusion, the following facts may be adduced. The effect of reducing the salts in a negative plate, as is well known, is to deprive it considerably of its detail-giving quality, and this is the object necessarily desirable to a certain extent in the so-called positive; and it surely occurs to one that the action of light through the camera is precisely the same for the positive as the negative, namely, to reduce most where the light has been most intensely reflected from the object. Now, if the positive plate were as susceptible to the weaker reflections as a negative plate, nothing but a clouded, misty-looking result could be obtained; therefore I think it is clear that a film poor in silver is the most favourable condition to give the brilliancy essential to the glass positive or tintype, since we see that abrupt crisp shadows and prominent lights are the ruling features characterising a positive effect. The positive (figuratively) so called is but a thin, hard negative, having an approximately white film. The designation "positive" was given when the discovery of taking photographs on glass was made in the primitive days of photography, owing

to their showing as a positive when viewed by reflected light. It is not for me to dispute the descriptive name; the excuse for briefly noting this is to point out the true nature of the reduction on positives taken through the camera, as it may save a little thought to those who take up their preparation. Nine-tenths of my exposures for glass positives and ferrotypes were made by contact against a transparency—this mode is not advisable for experiment, although expeditions. Granting that the minimum of silver affords the best condition for brilliancy in the positive, it may be useful to dwell further on the care needed in emulsification to prevent its giving the wrong colour when developed, as briefly stated in last paper.

It is apparent that emulsification will go on more rapidly when a small proportion of silver is used than if a larger be employed, and especially when there is also less gelatine present than is usual for negative plates; the emulsion being more aqueous, convection would make a more rapid interchange in the particles, thereby accelerating the emulsification, one hour perhaps sufficing to bring about the same degree of homogeneity or fineness of division as four or five in the case of an ordinary emulsion. With this in view, it is manifest that any increase in temperature would further control the time of cooking, high temperature producing the same effect in less time as longer cooking at a low temperature.

The addition of sodic sulphite to the emulsion after washing had a tendency to eliminate the yellow colour spoken of, giving a greenish white in its place. This latter colour was preferable to the former, but still necessary to be avoided. The means to the end was found to be in the withdrawal of the sodic sulphite from the emulsion. (This is the ingredient whose presence had to be dispensed with, as spoken of in last paper.)

Taking advantage of the similarity exhibited in the chemical action between emulsification and development already stated, I found that an increase in the quantity of sodic sulphite to the developer had the property of hitting the colour between the yellow tint and the green, which colour is a very favourable white.

It might be contemplated by some, that if one hour at 130° Fahr. be the limit of cooking, that this time ought to give as great rapidity as four or five hours would impart to a negative emulsion; but it is known to those experienced in plate making, as well as to those read on the theory of cooking and percentages of salts therein, that there is not the same surface of silver amenable to light and development; besides, there are special ingredients applied to negative emulsion to give sensitiveness that cannot be introduced in a positive emulsion without destroying the white colour, and, moreover, if there is not as much silver in the film as the gelatine is capable of suspending, it is known how rapidly sensitiveness decreases.

It is clear from this experience that we must choose between two evils, either to sacrifice brilliancy, and perhaps whiteness, for rapidity, or take brilliancy and whiteness at the sacrifice of half the rapidity—say, five times wet collodion to be the greatest rapidity compatible with good quality, and this is just the rather unsatisfactory stage to which it has been carried as regards rapidity, if it is looked on as a great desideratum; but supposing the greater part of tintype and glass positive work to be done with Gem and Victoria lenses, the exposure required outdoor is about half a second, in the studio about four to six times that—a period, under favourable circumstances, meaning the best actinic light essential for positive work. It is only in a dull light, as in the case of the collodion positive, that the sensitiveness apparently more than proportionally diminishes according to the decrease in the light. It is well known that collodion positives of the finest quality were only obtainable in the best light, and precisely the same tendency is exhibited in the gelatine positive.

Without further comment here, I give the latest modification of formula, and you may think little of it, as it reads but little different from an ordinary negative formula; nevertheless, this should not detract from its value, seeing that the end sought for is fulfilled. Suffice it to say that, given the conditions of light, apparatus, &c., eleven plates out of every twelve can be produced of uniform good quality, comparing favourably with the best collodion productions:—

Silver nitrate	300 grains.
Ammonium bromide	260 "
Gelatine	550 "
Distilled water	25 ounces.

Dissolve the silver in seven ounces water additional.

The usual methods of compounding are to be employed in this formula, any difference being in the treatment after washing; but to make the instructions more intelligible, the methods practised are here given. Soak the gelatine in the twenty-five ounces of water for five or ten minutes, dissolve at a temperature not above 130° Fahr., add a quarter of an ounce of absolute alcohol to the liquid bromised gelatine immediately before adding the silver.

The silver solution must be added in small quantities, with shaking on each addition. When compounded, return the bottle to the hot-water bath, and note that the temperature in the emulsion does not exceed 130° Fahr. Now allow it to cook one hour at the said temperature, after which pour it into a dish to set, then disintegrate the set emulsion, and wash in the usual way to remove the by-products. After draining the water from it, return it to the hot-water bath, and redissolve at a temperature of not more than 120°. The treatment now following is supposed to take an important part in giving the white film. Apply two drops hydrogen peroxide diluted with one ounce distilled water, and be careful not to heat above 100° until after the hydroxyl is added, and even then not more than 120°. This caution about the temperature in this operation is of vital importance, because it is known that heat decomposes the H_2O_2 into water and oxygen H_2O and O , hence the importance of low temperature at the moment of application. Once incorporated in the emulsion, I expect the function of the hydroxyl is to give up the atom of oxygen when in the nascent state to the silver salt, thereby altering its character and rendering it more amenable for a white deposit when developed.

So insignificant is the change from an ordinary emulsion, namely, the reduction of the salts and addition of hydroxyl, that it looks fit only for the credulous to accept; nevertheless a moment's reflection will remind us that similar improvements in photography have been characterised by apparently as simple modifications, and if the end is fulfilled, no matter how simple the means adopted. Of course the white film is not to be attributed to the modified emulsion alone, the constitution of the developer claiming half the credit of giving a white reduction. Much has been said lately about bleaching or whitening the film after development. Any attempts in this direction have not been very fertile in my hands. In fact I have not been able to get mercury, salts, or iodine to improve them in the slightest degree. Such treatment is surely superfluous, seeing that a film as white as a collodion positive can be got with simple alkaline pyrogallol.

As to the time occupied in manipulating them it can be even less than for negatives; fifteen minutes being ample for exposure, development, and drying. The white of the collodion positive is different to the gelatine production, the collodion showing a steel-white hue, while the gelatine has a warmer white, more of a straw colour: the latter has been appreciated quite as much as the steel-white of the collodion by old hands. No new departure can be successfully worked at first, not even by experts; one must be reconciled to spoil a few. Such failures serving to give a better knowledge of its character to the observing mind often leads to better success in the end. Considering this, the operator must not give up till rewarded with success, for they are just as simple as collodion positives, once the details of manipulation are understood.

Up till now we have been speaking mostly of glass positives, and it is needless to say that the same emulsion holds good for the ferrotype, as also does the same treatment in development; but it may be useful to dwell a little on the manner of coating the ferrotype plate. It was on account of the difficulty in coating the iron plate that I was compelled to try the glass positive; however, the method employed for coating the tintype may be accepted for what it is worth. Any of the plate or paper coating machines might be easily adapted for such a purpose.

Perhaps a description will sufficiently convey the idea without a sketch, and save considerable valuable space. Suppose two light wood frames, like the frame of a slate, hinged at the side, one frame being half chequed on the inside to allow a glass plate to rest therein, the other frame having a ridge of indiarubber glued to its inner edge so as to fit on top of glass plate round the edge where it rests on the half chequed part of the frame. It will now be seen that if the ferrotype plate be laid on to the glass plate, and the upper frame brought down or closed on it, that the indiarubber will press the iron round the edge and keep it flat on the glass till coated and set; a small hole is cut at level of the plate at one corner of the frame to allow the surplus emulsion to be poured off. This was the best means tried to coat them, but it was attended with much waste, due to their buckling with the hot emulsion. But no doubt a means of coating economically can be devised if a machine of the type used for coating paper do not answer. The usual method of coating negative plates applies equally well to the glass positives. Perhaps a heap of ambiguity about the theory of chemical action giving the white film has been advanced, and it may be prudent to simply give the formula for development and instruction how to use the same, without setting forth more such hypotheses, although it may be granted that trying to account for the reasons why may be of service to help further investigation. This is the plea for such speculations.

To get the best result on a positive the lighting has to be somewhat

different from a negative. First note that you have a very intensely contrasted white light, in order to get clear glass in the shadows; the time of exposure has already been specified. Development proceeds in the usual manner, only perhaps greater precision has to be observed in carrying it to the proper limit. The film being white makes detail difficult to discern, although a very much brighter light can be used. The developing formula, like the emulsion one, is but little different from an ordinary pyro developer, and consists of the following formula for development:—

A.	
Pyrogalllic acid	10 grains.
Water	10 ounces.
B.	
Liquor ammonia, s.g. '880	4½ drachms.
Ammonium bromide	2 "
Sodic sulphite (pure)	2 "
Water	20 ounces.

In addition to the sodic sulphite, carbonate and bicarbonate of sodium has been used in the developer as before mentioned, but recent experience has shown it to be superfluous; quite as good a white is got with the simple formula alone. The important object to be noted is in the balance between the pyro and ammonia solution; unless the proportions are accurately weighed and measured as specified, and the right quantities of A and B mixed together, the best white cannot be got. It is therefore to be emphasised that the developer must be regulated thus: Use for a quarter-plate four drachms of pyro solution to six drachms ammonia solution. Mix immediately before using. The image will appear in some time as a negative image. Continue development till the deepest shadows only show white unreddened bromide. If the light used be intensely white equal parts of A and B will give an excellent white. Fix in a freshly made weak solution of hypo soda; a small quantity of sodic sulphite may be added to hypo with beneficial effect, say one drachm in a pint of the hypo solution. After fixing wash three minutes under the tap, then immerse in spirit having a small percentage of tannic acid therein. Again rinse under tap, after which dry in the oven used for collodion positives, the tannic acid having fitted them for such treatment.

Let me hope that your readers will be unbiased at such a lengthy contribution on this subject, and that it might be permissible on the ground of its original nature, also that it may be of utility to our photographic brethren.

JOSEPH GRAY.

PHOTOGRAPHIC EDUCATION.

THE excellent endeavours made in many quarters to render the next generation of photographers in some respects an improvement upon the present do not, it seems to me, arouse that amount of interest which the undoubted importance of the subject demands. In fact, I am free to say that few, if any, of what may be termed the outside photographic public have any inkling of the extent to which posterity is being placed under an obligation; and I am strongly of opinion that lots of us who imagine ourselves to be well abreast of the times have only very hazy ideas about the matter. In particular, I must confess to being disappointed with a recent article on *The Education of the Children of Photographers*. I was led by the sound of the title to expect something of a profoundly instructive cast; but discovered that the writer simply hovered about his subject in a gay and *débonnaire* fashion which, although productive of bright and agreeable reading, does not, in my view, assist the development of any serviceable ideas in relation to the question, for after following his easy-flowing sentences along their pleasant course, and smiling at the brilliant display of fireworks with which they unaccountably concluded, the only impressions remaining on my mind were that he has little or no esteem for the facilities we possess for educating youths destined to earn their bread as photographers, and that the fine old crusted fallacy that the average middle-class educational curriculum of Continental countries is preferable to our own dies a hard death. True, the cost of education in France or Belgium is, or was, less than here at home, and a foreign language is a useful weapon in these days of fierce competition; but having admitted so much, I am unable to allow that there is any professional advantage to the lad destined to uncap upon fashionable beauties in Bond-street or Regent-street, or greasy provincials in Euston-road, from a scholastic training under alien masters, by alien methods, and possibly in purely alien subjects.

Switzerland, the Germanic Federation, and the Low Countries, are rightly famed for their technical seminaries and the fine craftsmen they send out, but I search the records in vain for the smallest evidence that photography in any of its branches is yet scheduled among the subjects taught at these schools. That being the case (of course I am

open to correction), I must demur to Mr. Harrison's advice in so far as it relates to the acquirement of a photographic education abroad, for the trifling reason that it is difficult, if not impossible, to get what is probably nonexistent, or at least nonapparent. I counsel photographers to avail themselves of the opportunities we possess at home for imparting the necessary technical knowledge to their sons. To show that we have the requisite facilities among us is partly my task on the present occasion.

The sorry sights presented by some of the highly paid leader writers of the Metropolitan daily papers as they recently gushed over the Cellerier-Mayall "discovery" must make all friends of enlightenment long for the time when the dangerous gift of a little learning, which those poor gentlemen seem at present to possess, shall have given place to a shred or two of well-grounded knowledge. In the meantime some one might take pity upon them and send them a copy of the expatriated Professor Burton's popular *brochure*, or one of Abney's forthcoming primers (originally penned for small boys), a diligent perusal of which, coupled with a little sober reflection, will possibly avert the recurrence of the wild blunders to which we are unfortunately growing rather accustomed. In a few years' time the present system—under which commentators upon abstruse matters in technical journals understand what they are writing about, and those who handle similar subjects in the more widely circulated daily newspapers do not—will probably be overhauled. Editors will have passed an examination in at least the elementary chemistry of photography at their universities; or, mayhap, the leader writers will not be handed the reins over roads with which they are unacquainted. Unhappily the diffusion of quasi-scientific information proceeds slowly. Four years since there appeared in this JOURNAL an editorial description of certain popular fallacies concerning the "New Instantaneous" process; among many well-informed people these same fallacies are still solemnly worshipped. A little photographic education would be very useful to the highly paid leader writer and the well-informed person; let us hope that by another four years they will have received it.

But as to the future professional: I believe we must dismiss as hardly feasible any plan for drumming photography into the undeveloped noddle of a schoolboy concurrently with the contents of his atlas and Colenso. It is a subject, or rather an aggregation of subjects, that from the mere operation of first conditions should be left until the destined photographer has got well forward in hobbledehoyhood. Midway in his teens the lad might be taught the grammar, or, at any rate, the alphabet of pictorial art, by being attached to a perspective class or sketching club, of which many abound. By this means an attempt will have been made to impart to him some, if only a little, of the artistic feeling which is so vital to his after success, for the better he can paint the better his photographs are likely to be. As an instance of the truth of this, I take from many the case of Mr. Vanderweyde, whose photographic portraits are so deservedly appreciated, and who is a skilful water-colour painter, to which, if memory serves me, an old Royal Academy catalogue bears testimony. When the boy has acquired the primary principles governing the laws of landscape and figure composition, advantage should be taken of the receptive condition of his intellect to introduce him to a practical study of the elements of photographic science expounded by competent teachers, whose services, in London at all events, may be readily availed of. Citing only a few instances that occur to mind, I can point to the photographic section of King's College, which has done excellent service in past days, and is still, I believe, in active existence, and to a similar class at the University College. Again, at that most admirable establishment, the Birkbeck, the theory of the science is expounded with commendable lucidity, and I rather fancy the City of London College is similarly distinguished. Independently of private "coaches," some of the minor societies in suburban London hold classes, whilst sincere eulogy must be bestowed upon the incalculably useful endeavours put forth by Mr. Howard Farmer at the Polytechnic. This gentleman's system of instruction is probably the most thorough, as it is unquestionably the most successful, in London. I have conversed with several amateurs whose knowledge of photography, gained by the efficient aid of Mr. Farmer, has been of a far-reaching and comprehensive nature rarely encountered elsewhere. Irrespective of the long list of honours gained at the City and Guilds and other examinations, many of his pupils are frequent metallists at the exhibitions, and it is but bare justice to mention the fact that as a professor of photography Mr. Farmer's success is without parallel. I have no data by me at the moment, and *Whitaker* is silent on the point, but I rather imagine that at some of the great technical schools in the chief northern and midland towns facilities for the study of photography are in existence. I think, however, that I have adduced enough testimony to establish

the fact that steady advances are being made towards the institution of systematic means for educating the photographer of the future, in respect of which it is charming to reflect that we are ahead of some of our quite-too-much-belanded foreign rivals. Recently a kindly clergyman made an offer to the Benevolent Association to adopt an orphan whose father had been a member of that progressively popular Society. This opens up the slight possibility of photographers having, like other bodies, in the remote future, schools for the particular education of their children; but in the meantime it is worthy of notice that in the Home for Little Boys at Swanley—a capitally managed charity—the children, among other things, are taught practical photography, and taught it well to boot. Straws prove the direction of the wind, and it may be safely averred that the present efforts to found the future well-being of photography upon such sure bases as the adequate instruction of the young will not be without beneficial results. At any rate, it is pleasurable to dwell upon the fact that photographic knowledge is being disseminated in so earnest a manner, and as this is the season of general jubilation, why, let us also jubilate, say I.

All scientific institutions and schools whose principal mission is the spread of technical learning may be strongly recommended to add photography to their list of subjects, for it is significant of the reception that attends any attempt to teach it that wherever a class is formed, or a series of lectures or demonstrations inaugurated, the results are invariably of a satisfactory nature to all concerned. Old as well as young hands are glad to avail themselves of the undoubted advantages to be gained from listening to an able exposition of the principles underlying a process or a formula. It is a common thing for operators and young assistants to frequent the institutions I have mentioned, and a year or two back Mr. Farmer's audience included one or two gentlemen whose names are honoured words in forensic circles, who had practised photography when the lecturer was in small clothes, all of which confirms the truth of the remark that we are never too old to learn. One praiseworthy benefit that is certain to come from the thorough system of tuition now in vogue cannot be passed over. Operators at present are merely fractional individuals, the term being elastic enough to cover the gentleman who only poses and exposes, the developer, the printer and toner, the spotter-out and the retoucher—say in all six. All-round men are scarce, but there is no reason why they should be. It is grotesque to find that in many establishments the operator is ignorant of printing, the printer unable to develop, and the retoucher a cut above taking the cap off. Assuredly this division of labour is not without its adverse results. To me it is inexplicable. Why, for instance, shouldn't a retoucher always be able to operate, and *vice versa*? Perhaps Mr. Barrett could inform us. Piecemeal photographers are absurdities. Operators although given charge of one particular department should be proficient in every branch, so that the developer knows as well as the printer whether a negative is flat or hard, and the retoucher can vary the exposures as confidently as the operator, and every one of them know the why and wherefore of the entire business.

But this is a wide subject and I can only glance at it in passing. I think we may reasonably hope for much solid good from the onward march of the attempt to found a system of photographic education for the mass. When a new race had sprung up, avowedly hostile to the present Joseph, possibly a little extraneous benefit will result to certain home industries now at the mercy of the terrible foreigner, for in the production of a new and original species of photographer we may by accident generate a revised edition of the genus manufacturer, in which agreeable contingency it won't be any longer necessary to ask the gentleman across the Channel to sensitise our paper because we can't do it properly in these islands, nor to sell us gelatine, bromide, pyro, silver, glass, mounts—everything, in fact, employed to make a picture—because we haven't sufficient enterprise to make them well and cheaply ourselves. Also, to follow Mr. Harrison's caustic lead, when we go to the National Gallery in a few years' time the vestibule may perhaps contain a fresh set of carbon prints of the high-priced gems upstairs, executed by a British and not a Continental house, with the explanatory legends beneath done into a language understood of the young man from the country and the young person out for the day. If these latter things do come to pass, what are the odds that our thanks will be due to Mr. Charles Lock Eastlake?

MARSTON MOORE.

SOME PHOTOGRAPHIC HERESIES.

[A Communication to the Photographic Society of Philadelphia.]

Any photographic theory or opinion opposed to the generally accepted one may be called a kind of heresy, and the heresy of one year frequently becomes the orthodoxy of the next.

The average professional photographer is generally a very conservative

individual, slow to accept anything new or to adapt himself to a new order of things, and yet possessed of more than the average share of ingenuity. This conservatism may arise from the scarcity of writers on photography who are good at making photographs, many of our best photographic writers being proverbially but indifferent photographers; the consequence of this is a large proportion of very fine writing, not without its value to the art-science, perhaps, but which is either misleading or ridiculous to the practical worker. Correct theory is, of course, very useful to the intelligent workman; but a false theory is neither ornamental nor useful, and a theory founded on imagination or superficial experiment is very apt to be false.

Many of us can remember when a collodio-bromide and gelatino-bromide emulsion experimentalist was regarded as a kind of fanatical searcher for the photographic philosopher's stone, and the possibility of producing a dry plate to equal wet collodion in sensitiveness was looked upon as on a par with photography in natural colours. The journals were half full of the heresy of emulsion photography, but nobody but enthusiasts would read such rot, until Charles Bennett announced photographing an interior by gaslight, and, what was more, showed the results before one of the London photographic societies, when the photographic world began slowly to awake to the fact that it was on the eve of a great photographic revolution. Then, as there was no denying the rapidity of the new gelatine dry plates, those who had mastered the wet collodion process, but had not the energy or ability to acquire at once the skill to do as good work by the new process, naturally blamed the process, and denied the possibility of its producing such good results, and there still are plenty of photographers in this city to-day who profess to believe the same.

When steel pens were introduced, there were for years many who still clung to the old scratching quill pen, but it was buried with them.

I propose to let wet collodion, for negative making, bury itself, having been among the first to dispense with it for that purpose.

Gelatine Plates.—Photographers generally are afraid of a very rapid plate for general work, they say that qualities, such as sparkle and latitude, have to be sacrificed to rapidity. I do not believe a word of it. I hold that a good rapid plate is capable of doing all that a slow plate is, and much more beside. Then why ride a mule when you may have a good horse for the same money? It is like some beginners I know who were very anxious to possess a lens of great rapidity; they obtained one, but never, under any circumstances, think of using it with any but the smallest diaphragms. They have two good legs, but are afraid to walk, and so hop about on one; or they may be likened to a man who uses steam power: when his boiler has been tested to 490 pounds, running with safety at 100 pounds pressure, he is afraid to work at more than 25 pounds, and, as a consequence, is always short of steam to drive his engine and machinery efficiently. Gentlemen, how many photographers are there who take full advantage of the great rapidity of the modern dry plate of to-day? Very few. Indeed, I hold they cannot do so with the appliances which are on the market to-day.

Sometimes we are told that "gelatine has ruined the business." What! enlarging the scope and power of photography has ruined it? Did the collodion process ruin photography? It ruined the Daguerreotype process; but photography? Not much. Gelatine may, and will, supersede collodion for negative making. It cannot ruin photography, but is a new power and blessing to the photographer and the world, and we do not yet know half its capabilities.

Development.—Another heresy of mine is concerning development. Development is not the simple matter some people would have us believe. It is a little science in itself, and not to be learned in a year. Now it is generally understood that slow development is the best treatment for a minimum exposure. My practice is directly opposite to that, inasmuch as I invariably use the most energetic developer I can compound and the plate will stand for such a case. I have no faith in homeopathic development as a remedy for general debility in the latent image. Did we use a weak developer for under exposure on wet collodion plates? No; but both strong and hot, because it was right in theory and practice.

The amateur photographic epidemic is regarded by many professional photographers with a great deal of misgiving, some even going so far as to say, "Amateurs are ruining the business." Now I have had considerable opportunity of forming a correct opinion on this point; and while I admit there is a certain class of mercenary plate spoilers, calling themselves amateurs, who expect their camera to earn its own fodder, or who go to Florida, or some other health resort, with the intention of making photography pay part of their expenses, yet I do not admit that calling themselves amateurs will make them such, in any sense of the word. They are professionals, to all intents and purposes, for the time being. Professional quacks, sailing under false colours. I have no doubt that they do some little injury to the business by cultivating the popular idea that photographs do not cost much to make, and that if a man has good instruments and plenty of light he has every requirement to make good photographs. This idea the genuine amateur is doing yeoman service to correct. See how he is educating the public taste to discriminate between good and bad photographs. Then look at the number of those who buy expensive instruments, and yet never, or only after much experience, produce good photographs. Is not that teaching the public (what they are slow to learn) that skill is an important factor in the production of good photographs? And when the public are able to recognise the qualities of

photographs, and appraise them at their intrinsic value, then the profession will be ruined to all incompetency, whether called amateur or professional, and the skilled workman will find his hands full and prices good.

I was out with my camera a few days ago, and a gentleman came by and asked, pointing to the camera, "What sort of pictures does that make, clear?" I must confess he did not make himself clear to me, so I answered, "That is for making photographs." He said, "But does it make them clear?" I replied, "That depends on how it is used; it is a question of skill, not tools; one man will carve better with a penknife than another will with the finest set of carving tools." While I possess the most complete outfit probably in this city, and set a high value on it, I should be foolish to expect my work to be good simply because I possess good tools.

CHARLES TAUSCOTT.

(To be continued.)

Our Editorial Table.

THE FERROTYPED AND HOW TO MAKE IT.

By E. M. ESTABROOKE. Fifth Edition.

New York: E. & H. Anthony & Co.

SUCH is the rush of beginners into the field of gelatine negative photography that we can quite anticipate many of the latest entrants not yet having had time to make themselves acquainted with any other department of the art, and hence to some the term "ferrotype" in its popularly accepted sense may still be strange. It simply means a collodion positive (in America, an Ambrotype) produced upon a blackened sheet of thin metal instead of upon glass subsequently backed with black varnish. Ferrotype portraiture is the sheet-anchor of those who practise at our seaside resorts or on the sands, and it has a good deal to recommend it. It is not difficult, it is cheap, the picture is finished while you wait; and, to crown all, if well done it is by no means to be despised in respect of its beauty.

We are glad to see a comprehensive work on this subject issued by the Messrs. Anthony. Mr. Estabrooke, in conjunction, as we understand it, with others, seems intimately conversant with the subject treated. But whoever may be the author *de facto*, there is no doubt of the work being an exceedingly useful one to all who practise this branch of photography.

After a brief historical account of the art of positive photography, special chapters are devoted to the glass house and its fittings, to collodion, the silver bath, developer, and manipulations. We have also a chapter on composition and illumination which is quite as applicable to the production of gelatine negatives as to ferrotypes.

It is well known that collodion positives when taken on ferrotype plates have a peculiar sinking or yellowing of the high lights. A portion of this manual is devoted to the remedies for this defect. One mode of avoiding this, we learn, "is by using a weak wash of tannin upon the plate before it is placed in the fixing bath. The solution of tannin eliminates all the sulphate of iron that may remain in the film after development and washing, and which, if left there, forms a compound with the cyanide which gives the yellow colour. Another mode of producing fine whites and rich velvety blacks, with freedom from fog, is to proceed as follows:—Make a saturated solution of protosulphate of iron, into which drop a solution of tannin, shaking the mixture all the while until the precipitate of tannate of iron ceases to be redissolved; then add drop by drop of a weak solution of nitric acid until the precipitate is dissolved and the iron solution becomes of a clear bluish colour. To one ounce of this add ten or eleven ounces of water and as much acetic acid as may be found necessary." This constitutes the developer. But we may add that a solution of bichloride of mercury properly made and properly applied, will impart a fine white colour to a dingy ferrotype.

WALKS IN THE ARDENNES.

By PERCY LINDLEY.

ALTHOUGH this handbook, which is published at 125, Fleet-street, is written mainly in the interests of cyclists and those who travel on foot or by rail with guns and fishing-rods, yet will it prove invaluable to the photographic tourist. Mr. Lindley has here got together in a most readable form a great amount of useful information of a topographical nature illustrated by numerous engravings.

THE MAGIC LANTERN AND ITS APPLICATIONS.

By L. H. LAUDY, Ph.D.

THIS work, which forms No. 19 of Anthony's Photographic Series, is written by a gentleman well known in New York scientific circles, and is published by E. & H. Anthony & Co.

In his preface the author says that he has endeavoured to embody

in as concise a form as plain language would permit, a thoroughly practical description of each of the more important lanterns and accessories that have come under his personal observation during some fourteen years of practice connected with the School of Mines, Columbia College. Dr. Laudy carries out his endeavour in a very excellent and comprehensive manner by describing the various lanterns obtained in commerce. The higher class of lantern for scientific projections is also fully treated of, and drawings are given of the vertical lantern with rectangular prisms, the electric and gas microscope, the spectrum projector, and the appliances for utilising polarised light. The work is a valued addition to our lantern literature.

IMPROVEMENTS IN PHOTOGRAPHIC PRINTING MACHINES.

No. 10,770.—JOHN URIE, senior, and JOHN URIE, junior, 83, Jamaica-street, Glasgow, Lanarkshire.—*August 23, 1886.*

OUR invention has reference to photographic printing machines, which print the pictures from the transparent negatives on the sensitised paper automatically in long lengths by artificial light. And the invention comprises a new or improved construction, or arrangement and combination, of the mechanism for so automatically printing the photographs in said printing machines:—That is, of the mechanism which performs all the necessary operations, of putting off and on the light so as to give the paper the proper period of exposure to the light, and also release the paper from between the negative and its pressure pad, and shifts the paper the required distances after each print for the new picture, and presses it against the negative again, all intermittently and in proper sequential time by the machine or mechanism itself when it has been set to work, with the roll of paper in place.

The nature and novelty of the invention, or construction and arrangement of the mechanism, consist all as follows:—The roll of sensitised paper and all the working mechanism are enclosed in a moderately sized, longitudinal, rectangular box, having the aperture in the middle of the top or lid, for inserting and securing the set or "nest" of various sized frames to fix the negatives in; the gas or other artificial light used being arranged over the aperture and negative, so as to be raised further from or lowered near to the negative to regulate the strength of light desired for the work or density of negative in hand for the time being. The roll of sensitised paper to be printed is mounted on a spool or bobbin in the upper part of one end of the close dark box, and led along close over its pressing pad and under the negative and opening in the centre and top of box, on to and round a large measuring drum; through and between this and a spring gripping roller, over the latter, either down into a deep dark chamber or recess for receiving the printed strip or web, or this may be led, as so printed and measured, on to a special winding-up drum or bobbin at the other end of the box under the supply bobbin, all so far mounted much as in former machines, but with the journals of rollers or drums carried by bush bearings in the sides of the box. But by this invention the whole mechanism for performing and regulating the work and movements automatically is new, and much more simple than in former machines of this kind. This mechanism requires no special frame, and consists of clock mechanism or reducing wheel gear driven by a chain and weight, or by an endless chain, with weight hooked on to one line of the chain and shifted to the top as it runs down to the bottom, saving all winding up; which arrangement is also applicable for driving the paper-measuring or the taking-up drums direct. This clock or motor gearing, which actuates the whole regulating mechanism, could also be driven by a strong spring and be wound up from time to time as required, and would be regulated to various speeds by a fan spindle with radial arms and air vanes outside, which could be shifted out and in radially by hand on the arms, to suit the speed of the gearing and motor desired, and also of the radial pin barrel actuated by it, to the time of each revolution of this barrel desired to actuate the lever mechanism, which gives and regulates the necessary intermediate motions sequentially as hereinbefore referred to. This time speed pin barrel, turned at any regulated speed by the clockwork wheel gearing and regulating fan as described, makes a turn in, say, from one to three minutes, and has four, five, six, or other number of annular rows of pins, all of equal lengths; the first set commencing with one pin in the circle, and the second with two pins in the circle, and so on, all so as to give from one to six actions to the lever, according to the set of pins it is brought opposite. The journal bearings of this pin barrel, and its actuating clock mechanism, require no special framing, but are secured to the bottom of the box inside, and the barrel is set transverse-wise near the middle of the box, and has ranged parallel to it a double armed crank or bar lever mounted loose on a transverse horizontal

spindle, which traverses through its crank journals, and works in slide journal bearings in the sides of the box, all parallel and horizontal to the axis of the said pin barrel and a little in front of the pins. This horizontal spindle has a short adjustable lever fixed on it inside the box, projecting out in the parallel plane of the pins, so as to be actuated by any set of these pins, according as the spindle is drawn forward in front of the box by a handle on its outside. The lever of this spindle would rest on the long crank bar, carried by the double arm on its spindle, and depress this also, as well as its actual lever, each time a pin came round in the circle, and this double-armed lever would carry a long weighted lever, preferably at the back end, and which would have a counterbalancing weight on it, which would always bring the lever back to its normal position, while it would have another lever which would actuate the short lever of a gas tap or valve, so as to shut it each time the pin came round. This double bar lever would also at each end carry a vertical reciprocating frame in guides on the side of the box, secured to and carrying the pad on the top of them, for pressing the paper against the negative, with regulating spiral or other springs on and between joint stems on the lever, and on the under side of the lower traverse bar of the guide frame; all so that, as the gas was shut off by the action of the levers, the pressing pad and frame carrying it, would be lowered so as to allow the paper passing over it to be drawn along the measured distance required over its barrel. This measuring of the paper is effected by another lever on the front of this double-armed bar crank projecting out below the rim of the measuring drum, preferably on the front end close inside the box, with a vertical acting oscillating pawl on it, projecting upwards so as to take into divisional projections on the rim of the measuring wheel; these projections being so divided round the rim of the wheel as to decide the length of paper to be measured off at each action. The vertical projecting pawl on the point of the lever is always pressed outwards by a light spring on it, so that, after each action of the lever, it is easily drawn down by the counterbalance weight on the other end of the double crank bar, clear of the projection on the drum it had stopped, and so leave the barrel clear to be turned another measured division the next time it was left free, to turn by the releasing of the pad and paper, above the vertical oscillating frame, and come round against the pawl on the stop lever at the next operation. The falling of the balance weight would also raise the frame and grip the paper between the pad and the negative just before the pawl, on the stopping lever, released the wheel for its next action as described; the balance weight also raising the lever which had shut the gas off, and allow a counterweight or spring acting on the short lever on the gas tap or valve to open it again to the regulated distance and position, ready for the double crank lever to again shut it off, when the pins in the barrel came round and actuated it through the regulating lever on the traversing spindle.

Instead of the double-armed lever drawing down the pad under, and to release the paper as described, the pad could be made stationary, and the lever made to lift the printing frame in an equivalent manner off the pad to release the paper, by its two ends direct, or mounted on hinges along one side, the lever or springs not acting to free the paper until the gas lever had shut the light off, all as described under the first arrangement.

[The complete specification is copiously illustrated.]

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
July 26	Great Britain (Technical)	5A, Pall Mall East.
" 26	Bolton Club	The Studio, Chancery-lane, Bolton.
" 27	Photographic Club	Anderson's Hotel, Fleet-street, E.C.
" 28	Liverpool Amateur	Royal Institution, Colquhoun-street.
" 28	Oldham	The Lyceum, Oldham.
" 28	London and Provincial	Mason's Hall, Basinghall-street.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

LAST Tuesday night a special general meeting of the above Society was held at 5A, Pall Mall East, London, Mr. James Glaisher, F.R.S., President, in the chair.

The meeting revised a portion of the rules of the Society and then adjourned the remainder of the work until the second Tuesday in October.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

ON Thursday night, July 14, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. J. J. Brignishaw presided.

Mr. J. T. TAYLOR read a published letter by Mr. Prestwich, speaking of the warm reception given by Glasgow photographers to their photographic visitors at the recent Convention.

The CHAIRMAN said that everything had been done at Glasgow to promote the pleasure and comfort of the visitors, and that at Edinburgh they were welcomed by the photographers, taken about in conveyances, shown over places of interest in the city, and entertained at luncheon.

Mr. W. M. ASHMAN suggested that the Hon. Secretary should write to the corresponding member of the Association in Paris, Professor Stebbing, and ask for full particulars as to what was being done in relation to the suggestion of the Photographic Society of Douai to convene an International Congress of Photographers in Paris during the Exhibition of 1889.

Mr. A. L. HENDERSON thought that the English Convention might meet in Paris in that year.

The HON. SECRETARY stated that he would write to Professor Stebbing for information. He then laid circulars upon the table relating to an amateur prize competition inaugurated by the Stereoscopic Company.

Mr. A. MACKIE said that the name of the Photographers' Benevolent Association had been entered on the circular without its consent.

Mr. F. W. COX thought it to be a pity, if amateurs wanted an exhibition, that they did not inaugurate it themselves and keep free from trade influence.

The CHAIRMAN wished for a definition of an "amateur."

Mr. H. M. SMITH said that directly a man took money for anything photographic he ceased to be an amateur.

Mr. W. E. DEBENHAM said that it was a pity that the question of amateur and professional had ever been raised; before it was recently raised photographers had always been working amicably together. He should like to gather the opinion whether the words "photography in colours" could be applied to photographs artificially coloured by hand without misleading the public.

Several members spoke upon the point, after which the CHAIRMAN said that the meeting seemed to be unanimously of opinion that the term "photography in colours" could not be justly applied to photographs artificially coloured.

Mr. L. MEDLAND exhibited photographs of animals taken by himself at the Zoological Gardens in Regent's Park. He had been disappointed in trying to take the bears; they had had so many buns the day before that they would not climb the pole.

Mr. SMITH asked if the diaphragmatic shutter could be applied to any form of lens; could it be applied to Darlot's cabinets of lenses?

Mr. TAYLOR replied that it could, because these lenses were all properly ratioed in their cells.

Mr. W. ENGLAND liked the diaphragmatic shutter better than any other he had ever used.

Mr. MEDLAND exhibited a print of the royal train as it passed through Barnet the night before; it had dark spots upon it where emulsion had been spilt upon the back of the negative plate. Why was that?

Mr. J. B. B. WELLINGTON replied that it was because Mr. Medland had held the plate up before the dark room window to see if it were fully developed, and the light being too strong had fogged the image except where protected by the spots.

Mr. DEBENHAM said that it might also have been caused by stray light in the camera slide.

Mr. Medland exhibited a pinhole negative much blurred.

Mr. DEBENHAM remarked that the hole had been too large; blurring was more noticeable when the plate was near the hole than when far from it, loss of sharpness being more striking the smaller the picture.

Mr. HENDERSON thought that the hole might have been really a tube; the hole should be pricked in something very thin, such as a piece of tinsel.

Mr. DEBENHAM said that some very presentable work had been done with pinhole cameras in France.

The Chairman laid on the table the prospectus of the coming Exhibition of the Photographic Society.

The meeting then broke up.

SHEFFIELD PHOTOGRAPHIC SOCIETY.

THE monthly meeting of the above Society was held on the 5th instant.—The President, Mr. T. S. Yeomans in the chair. There was a good attendance.

The PRESIDENT asked the Committee appointed what had been done towards securing a photograph of each member, with a view of so combining them as to form a photographic group of the members of the year.

Dr. MORTON replied, and gave information which appeared satisfactory.

A discussion arose on the keeping qualities of dry plates, in which Messrs. Yeomans, Morton, Gilley, and Platts, took part. The conclusion arrived at was that a bromide plate would keep indefinitely and in good condition if kept from damp and air, and that the metallic stains which sometimes appeared on a plate were due to the action of the impure atmosphere to which they had been exposed.

Mr. MALEHAM offered a dozen plates purchased six years ago, which had never been opened, to any members who would test them.

Two competitions took place at this meeting, namely, the usual monthly one, subject, "Sunlight and Shadow," and one for the prize offered by the President for "The most original and artistic photograph taken on the Haddon Hall Excursion." In both competitions the pictures exhibited praiseworthy attempts at the artistic treatment of the subjects in hand. The following are the results: "Sunlight and Shadow," 1st, Mr. Joseph Taylor (Hon. Secretary); 2nd, Mr. T. G. Hibbert. "Haddon Hall," Mr. T. G. Hibbert.

BIRKENHEAD PHOTOGRAPHIC ASSOCIATION.

THE ordinary meeting of the above was held in the Free Public Library on Thursday evening, the 14th instant.—Mr. J. A. Forrest, President, in the chair.

Mr. H. Williamson, Dr. Stansfield, Mr. T. S. Mayne, and Dr. Proctor, were elected as members.

The Secretary had an interesting exhibit of a ball-headed camera stand invented by Mr. John Brown, a member of the Belfast Photographic Society; it was freely criticised, and pronounced a great improvement on stands somewhat similar in principle. The inventor had used it extensively in yachting excursions and in places where the ground was exceedingly rough and uneven, but had never found, no matter what the position of the tripod, any difficulty in getting the camera almost instantly properly placed and at the same time perfectly rigid. The ball to which the camera is screwed is of wood, and is held by a series of metal clips, which are contracted by pressing a small lever on the tripod proper, being then immovable until released. The ball and metal work is light, considering its strength, and occupies about the same space as an ordinary tripod head.

A view finder from Messrs. Newton's, Liverpool, giving the image unreversed, and a roller slide of Messrs. Morgan & Kidd's with Rogers's registering indicator, were also exhibited, the latter an addition to the existing form of slide, being a circular brass disc numbered for twenty-four exposures, which revolves with the roller holding the film, and then locks itself when the exact quantity has passed off.

Mr. B. J. Sayce exhibited an album of prints made entirely from paper negatives which had not been oiled; the results were very fine, and had Mr. Sayce made a secret of the matter it would have been impossible to have said that they were not from glass, printing without rendering the negatives translucent seeming to hide the granularity of the paper, a defect the oiling seems only sometimes to make apparent.

Appropos of paper, Mr. P. LANGE and Dr. KENTON, of Chester, wished to lodge a complaint against the Eastman Company. No firm advertises their goods more largely, yet when a supply of either negative paper or stripping films is required it is almost impossible to get them, the demand seemingly being in excess of the supply. They had both been put to great inconvenience on several occasions, and thought Messrs. Eastman should take steps to rectify the matter, especially so now that the height of the season is on.

A number of prints of the race in the Mersey between the yachts "Thistle" and "Ilex" were exhibited by various members. Mr. J. H. Day had a number of Marple Hall, near Buxton, which were exceedingly effective; whilst the President showed what a veteran he was in the art by exhibiting an enlargement of the moon done by himself so far back as February, 1854, in conjunction with Mr. Hartnup, the Astronomer to the Mersey Dock Board. The exposure had been one minute and a half, the resulting negative giving a figure of only a little over an inch, yet so perfect was it that the enlargement was quite sharp, showing all the principal craters and various surface markings.

The Jubilee excursion to Trefriw was productive of an immense number of prints, a collection of which was made for presentation to Alderman Sannelson, who had originated the trip, and was to have entertained the members, but was prevented by sickness at home; this, however, in no way interfered with the success of the trip, the only *contretemps* of the day being the deluding of a number of members into changing their plates in an improvised dark room at the hotel, with the result that they proved hopelessly fogged on development.

Mr. LANGE gave an interesting practical demonstration of the working of Eastman's stripping films, he having been giving them an exhaustive trial of late, which was listened to with much attention, and created some controversy on the best mode of working. He had produced some most satisfactory results, but had to depart in some respects from the recognised formula. Coating the glass plate with collodion not acting, he had dissolved four grains of unvulcanised Para bottle rubber cut fine in one ounce of pure benzine; this when brushed quickly over the plate gave an exceedingly even substratum. Naphtha may be used in lieu of benzine, but when it is the quantity of rubber has to be increased to six grains. Mr. Lange spoke of the difficulty of getting it to dissolve, requiring from two to three days to attain that result.

Mr. H. N. ATKINS suggested that if, instead of the rubber as sold in strips in the shops, he got the ordinary article and used the white inner portion, it would dissolve much more rapidly, not being affected by the atmosphere, which had a tendency to make it hard.

Mr. LANGE also threw out as a hint to the uninitiated that the films required to be developed to about double their seeming density, as otherwise when they came to be printed from they would be found to be too reduced to give a satisfactory result.

At the close of Mr. Lange's demonstration an interesting discussion took place between him and Dr. Kenyon on the merits of film photography.

The meeting then broke up.

DERBY PHOTOGRAPHIC SOCIETY.

THE members of this Society had an outdoor excursion to Monsal Dale and Cressbrook on July 2, which was well attended, and some excellent negatives obtained.

On Saturday last the outing was to Rowsley and Haddon Hall. The attendance was a very good one, and although a severe thunderstorm visited the district and marred the proceedings during a portion of the afternoon, upwards of sixty plates were exposed in and about the Hall, where subjects for the camera are abundant.

The next outing will take place on July 30 to Wingfield Manor.

GLOUCESTERSHIRE PHOTOGRAPHIC SOCIETY.

THE second meeting of the above Society was held at the School of Science, Gloucester, on Friday, July 1, 1887, to receive the report of the Provisional Committee appointed to draw up a set of rules, and also to elect officers.

The following were appointed:—*President*: Mr. George Embrey, F.C.S.—*Committee*: Messrs. W. J. Jenkins, W. B. Wood, A. H. Pitcher.—*Hon. Secretary and Treasurer*: F. H. Burr, 8, Midland-road, Gloucester.

The first excursion took place on Friday, July 8, Ledbury and district being selected, the party being conveyed by brake. Ledbury was reached in good time, and the afternoon was none too long to secure photographs of its market house, church interior, picturesque courts and alleys, and fine timbered houses. A capital spread at the "Royal Oak," a successful ballot for five new members, and a pleasant drive home in the cool of the evening, completed a most successful and enjoyable excursion, the average number of plates exposed by each member being eleven.

NORTH SURREY PHOTOGRAPHIC SOCIETY.

AT the last meeting of this Society, on July 6, Mr. WOLFF, who occupied the chair, explained and demonstrated the method of manipulating his self-adhesive mounting boards. These mounts are of the usual gilt bevelled-edge description and are coated with an adhesive substance which when dry does not alter their appearance in any way. The prints to be mounted, if dried, are soaked in water for a few moments, or are taken from the last washing, and placed between blotting paper to remove superfluous moisture. They are then placed in position on the mounting board, covered with a piece of paper, and smoothed down with the hand.

It was announced that the Hon. Secretary offered a prize of one guinea for the best series of six prints from this year's negatives, to be awarded at the first meeting in December.

An outdoor meeting of the Society was arranged for Saturday, July 30 at

Cassiobury Park, Watford. Trains from Euston at one o'clock and forty minutes past one.

The Society then adjourned to meet again on October 5.

HALIFAX PHOTOGRAPHIC CLUB.

THE annual day excursion of the Club took place on Monday, July 11, the place selected being Balton Woods, Wharfedale. The early part of the day turned out to be most unfavourable for photographic operations, being dark and cloudy, with heavy showers, accompanied with strong gusts of wind. A party of fourteen, however, believing in the old and trite saying that fortune favours the brave, mustered and drove from Skipton to the Abbey, after a rather dispiriting railway journey. Towards noon the sun broke through the clouds, and a change for the better was hopefully predicted, and fortunately verified later, for a very enjoyable afternoon was spent "by meal and stream, in foxglove dells and ferny combs." Between sixty and seventy plates were exposed, and, it is hoped, some good pictures bagged, to remind one in days to come that every cloud has its silver lining. The party drove back to Skipton in the evening, where a very bountiful repast awaited them at the Midland Hotel, which soon went a long way to make all feel well satisfied with themselves.

PHOTOGRAPHIC SOCIETY OF IRELAND.

THE annual outdoor meeting and excursion of the above Society took place on Thursday, June 30, to Lugala and Lough Dan. The party met at Bray at about half-past nine a.m., on the arrival of the various trains from Dublin and Kingstown, and started at once in the vehicles which were in waiting for Lugala and Lough Dan. The day was all that could be desired. Cameras were set up and various "bits" taken, every one seeming to find something to his taste, and a couple of hours were spent very pleasantly in the vicinity. When the lake was reached the whole party removed their clothing and had a plunge in its cool waters, from which they emerged very much refreshed. Boats were waiting here for the party, who embarked and proceeded to the lower end of the lake, where the cars were waiting, and drove to Roundwood, where a repast was provided at Keane's Hotel. The party then returned home, having enjoyed a pleasant day and exposed seventy-six plates of all sizes from 12x10 to quarter-plates.

Correspondence.

Correspondents should never write on both sides of the paper.

PRESENTATION BY M. DUBRONI OF A SMALL HAND CAMERA.—SEVERAL NEW LENSES AND A FOCUSSEING GLASS PRESENTED BY M. BALBRECH.—A NOTE-BOOK FOR AMATEURS.—PHOTOGRAPHIC PUBLICATIONS BY M. GAUTHIER-VILLARS.—PHOTO-SCULPTURE.—A NEW INSTANTANEOUS SHUTTER.—A DEMAND FOR PORTRAITS OF THE FATHERS OF PHOTOGRAPHY.—LANTERN VIEWS OF CONSTANTINOPLE.

M. DUBRONI exhibited an apparatus which he calls "photo-éclair." It consists of a circular camera about two inches thick; it carries five small plates about one inch square, which, by turning the back of the camera, are made to come one after the other before the lens. To the lens is adapted a revolving shutter. The apparatus is intended to be held in the hand, so as to get a shot when the occasion presents itself.

M. Balbrech presented several of his new lenses, which he said were made by combining "two flint with one crown;" the three are then joined together with Canadian balm, "Baume de Canada." Several of the members spoke highly of these new lenses.

The same gentleman presented a focussing glass, far superior to those in general use here.

Two advantages can be cited. When set for the sight of the owner, said the inventor, a friend can make use of it without it being focussed once again; this is obtained by means of a sliding rule engraved upon the double telescope of the apparatus. When the instrument is placed upon the ground-glass of the camera in order to enlarge the image, the inventor says, as his instrument is achromatised every line in the field of the focussing glass is faithfully delineated: this is the second advantage.

A pocket-book was laid upon the table containing useful information for amateurs—a little good advice as well; one of which is, never to be satisfied by putting a number on the dark slide and counting upon one's memory to know if the plate contained therein be exposed or not. The only sure and practical method is to paste a thin band of gummed paper over the top of the shutter of the dark slide; if the paper is intact the plate has not been exposed, if the paper is torn it is a certain proof that the slide has been exposed.

M. Londe criticised the idea of pasting a number on plates to be developed. The best and most simple method, said he, is to write on the bottom of the sensible surface with a lead pencil; the plate may be developed, fixed, and manipulated with the writing and cannot be obliterated.

A certain number of photographic publications were presented, among others a *Manuel à l'Usage des Officiers, des Explorateurs, et des Touristes*, par le Commandant E. Joly; a *Manuel pratique de Photographie instantanée*, par A. Agle; *La Photographie Astronomique*, par M. Le Contre-Amiral E. Mouchez, Directeur de l'Observatoire de Paris. These books have just come from the press of M. Gauthier-Villars, the well-known and highly-esteemed photographic publisher of Paris.

I note here that M. Lazard sent in a communication on the process he employs to obtain busts, statues, &c., by means of photography (photo-sculpture). As this gentleman's letter was very long it was not read, but put aside to be published in the *Bulletin*.

M. Martinet presented a new instantaneous shutter, being the best, I think, I have ever seen. It opens from the centre and closes in the same manner. Its place is, therefore, indicated in the centre of the lens between the two glasses. The inventor says, "*La pose est facultative*;" in fact, any pose to the rapidity of the two-hundredth part of a second can be obtained. But what pleased me most in the instrument is, that the full opening can be obtained in a fraction of a second and be kept open at the will of the operator. He has only to press the indiarubber ball, it closes instantaneously. Many other features and advantages could be enumerated, but difficult to understand without drawings or seeing the instrument.

One of the readers of THE BRITISH JOURNAL OF PHOTOGRAPHY writes me that he is preparing for publication a history of photography. I should very much like, said he, to illustrate it with the portraits of Daguerre, Niepce, &c. This gentleman asks me to assist him in getting photographs or portraits of the masters of our art. I laid his request before my colleagues. The President kindly said that the Society would be happy to endeavour to obtain the desired proofs. I see, by THE BRITISH JOURNAL OF PHOTOGRAPHY of July 1, that Charles Mason, in the paragraph, *Our Fathers: Where are they?* complains of the difficulty to obtain portraits of the old masters of our art. Let all assist these gentlemen in their praiseworthy endeavours to illustrate their historical works on photography. The penalty of such publications is the sole cause why Mungo Ponton's name is unknown to many of the admirers of photography.

The Society broke up after an interesting lantern exhibition of the views of Constantinople, said views having been obtained by a little hand apparatus by a passing amateur.

PROF. E. STEEBING.

59, Rue des Batignolles, Paris.

HALATION AND ITS CURE.

To the Editors.

GENTLEMEN,—I am glad to see by your leader of July 1 that you are giving to this defect in photographic negatives your earnest attention, and trying after an experimental remedy. It has been on my mind, and under experiment also, for some months, and I would like to give you the result of my trial of a remedy which I think is very effectual as a cure, very cheap in application, and very convenient in the rapidity with which it can be used in the preparation of negatives by "backing." I have not a doubt in my mind after comparison of a number of negatives of landscape subjects taken with and without "backing," that it is a very decided improvement to the result on all negatives, no matter what the subject may be, or length of exposure given; but in cases where *long exposures* are imperative, such as interiors or outdoor subjects in shaded situations, where exposures of a minute or upwards are necessary, and where the thin boughs of trees are usually in strong relief against the sky, the difference in quality of such negatives when "backed" and not so treated is very marked and unmistakably in favour of the "backed" plate.

I have tried the collodion stained with aurine and roseine. It is a very good "backing," and easily applied; but in the *rather dim light* of the dark room, in which it is advisable only to expose the plates for preparation, it is not easy to coat them perfectly without spilling some of the contents, either on the hands or workbench, or possibly over-running the edge of the plate on to the face, to its utter ruin; and the stain of the aurine, &c., is so very strong if it should happen to touch the hands or the clothing of the operator that I found it rather too great a trial of patience to continue its use. Then, again, it is rather difficult to scrape off perfectly, which should be done before development, in order to be able to judge properly as to the density before fixing.

The remedy I have settled down to is not new, and has been recommended before, but it is the *convenience* of its use that recommends itself to my taste. Dissolve as much common asphaltum in benzole as will make it the consistency of thin cream, lay the plates face downwards on a sheet of clean paper (blotting in preference), pour a *small pool* of it into the centre of a plate, and spread it quickly over with a small, flat, soft brush to within, say, a quarter of an inch of the edge of the plate, and let it dry; by the time three plates have been coated the first is dry enough to rear up on edge and set aside on a shelf to harden—and by the time seven or eight plates have been so treated all tackiness has left the first plate, and it can safely be put away, either in the dark slides or in a grooved box. So much, then, for rapidity and convenience in preparing the plates. As to cure of the fault of "halation," I have put it to the following crucial test:—I exposed a plate so "backed" to the interior of a church for a period of *two hours*, and obtained a very perfect negative, without a trace of "halation" about the three Gothic windows in the chancel (the centre of the picture), which is a far more severe test of efficiency than even tree-boughs against the sky, for which also it is a perfect preservative.

It appears to me that the warm brown colour of the asphaltum in optical contact with the glass plate *absorbs every ray* which passes through the film, and allows no refraction whatever to take place.

Some one may ask, "How about removing it before development?" Nothing is more easy, or more promptly done, if the plate is held at a steep slope in the left hand, with a corner pressed firmly against the breast, and a broad, sharp chisel used with the right hand, commencing at the bottom and working upwards. The dry asphaltum falls off in a heavy powder on to the floor of the room, and may be swept up and removed by daylight most readily. I can easily clean off the "backing" from a 12x10 plate in two minutes by such means, and leave the plate practically (but not chemically) clean for development. There is nothing in the minute quantity of asphaltum left on the plate to act injuriously in any way on the developer, which can perhaps hardly be safely said of the aurine and collodion, if not absolutely cleaned off, as that is such a powerful stain that the gelatine film might suffer by absorption of colour if any escaped into the developer. If your researches result in any better or more convenient method, I shall be pleased to learn it; but I doubt whether anything can be found more readily applied or removed, and so conveniently rapid in its "setting" property after application to the plate, as one does not care to have to wait (for perhaps half an hour) for the drying of any aqueous solution of dextrine, gum, and sienna coating, which may be effectual, and easily removed by a damp sponge, but which takes some time to set firmly enough to make it safe to put the plates into the dark slides.—I am, yours, &c.,

GEORGE BANKART.

FINDERS AND FOCUSERS.

To the Editors.

GENTLEMEN,—Was Mr. S. D. McKellen speaking in jest or in earnest when he said at the Convention that Mr. Lionel Clark's apparently original and certainly useful method of converting the focussing screen of the camera into a finder, using a separate lens, was covered by a patent obtained by the speaker?

If Mr. McKellen has really patented a finder and focuser, the salient point of which consists in having a separate lens and ground-glass connected with the working lens and sensitive surface, and acting in harmony with them, then I have only to say I am sorry for his patent, as there is no one conversant with the past history of photographic cameras, or who is a careful reader of your JOURNAL, who does not know that such has for some years been done. Will Mr. McKellen please say what he claims?—I am, yours, &c.,

JUMELLE.

THE LATE CONVENTION.

To the Editors.

GENTLEMEN,—A small error has got into the report of my paper read at the Convention. In line fourteen (page 438), instead of eighty "per cent.," it should read eighty degrees.

I heartily endorse all that Mr. Prestwich has said respecting the success of the Convention. Great praise and thanks are also due to the Glasgow ladies, especially to Mrs. Mason, who did so much for our comfort and enjoyment by placing the rooms of her hotel at our disposal for Council meetings and other purposes.

I much regret that some journalists have thought fit to attempt to discountenance the Convention, but trust, if they are open to conviction, that they will yet see the usefulness of these meetings.—I am, yours, &c., 49, King William-street, London, July 16, 1887. A. L. HENDERSON.

[Mr. Henderson evidently, for the moment, loses sight of the fact that no movement whatever of an advance nature has ever yet been made that has not had to encounter opposition and obstruction, either open or veiled.—Eds.]

THE RIGHT TO THE NEGATIVE.

To the Editors.

GENTLEMEN,—The non-acceptance of the lady's challenge to discuss the question of the ownership of the portrait negative by Mr. Coan appears to have brought the correspondence to an end. I had hoped that you would have reviewed the arguments or statements made by the different correspondents and given your remarks thereon. As you have not done this, but have expressed yourselves in favour of the custom of the trade as the unwritten law to be taken as our guide when no written law exists, perhaps you will permit me to make a remark or two on this custom.

Custom whose origin is obscure from time, or whose origin, if discovered, is based on equity, can alone be held in valid law. Now the origin of the trade's claim to the portrait negative is not lost in obscurity; it belongs to our own times, and we know it. Its origin arose first in the sitters' ignorance of the negative, or of its nature and power, and, secondly, in the trade's readiness to take advantage of such ignorance. Not an honourable origin. Proof of these statements are not wanting. Let me quote from your issue of April 29. Mr. Barber, of Shetfield, writes: "Query, Why should photographers be supposed to use negatives at all? Are we obliged to say how we produce our work?" Again, in your issue of June 10, Mr. A. L. Stevenson, of Durham, writes: "When a dozen portraits of any size are ordered, the sitter is seldom, I believe, able to prove that there was a negative. By general knowledge he may be aware that he cannot be photographed without one, but he never sees it, unless by special goodwill of the operator, and if he gets his dozen

cabinets that is all he asked for, and all that was promised him, or that he can prove is in existence."

Can a custom so based be held as good law? In my opinion it ought not. In the legal cases you cite the claimants were equally wrong. They sued for what did not belong to them. In your issue of June 17 your correspondent "Mac" writes, "What now about the negative? The glass and the film are undoubtedly the photographer's, and the impressed portrait on the film belongs as undoubtedly to the sitter—a joint partnership." Now this joint partnership is inseparable; a dissolution of it cannot take place without an arrangement between both owners, unless the negative be destroyed. The photographer has, however, possession, and to abuse his trust in any way would be dishonest, which no custom of trade could justify.

Respectable photographers do not abuse their trust, and as your correspondent "Mac" refers to this I shall again quote from same letter. He writes, "It has been the custom for photographers to preserve and retain the portrait negative, not for their own benefit only but for the benefit of their clients also, from whom an expressed wish that it be no longer retained would receive immediate attention. I am an amateur of the old wet date, and this has been my experience of my professional friends, with some of whom I have been long intimate. They are good, generous men—men of strict honour."

All praise to "Mac's" friends and to the many hundreds throughout the country like them—equally good, generous, and of strict honour.—I am, yours, &c.,

J. F.

FIFTY SITTINGS FOR A PORTRAIT.

To the Editors.

GENTLEMEN,—Mr. R. Barrett, in the course of his observations in No. 1417 of this JOURNAL, says that Sir Thomas Lawrence and Sir Joshua Reynolds have repeatedly had so many as fifty sittings for a portrait, and that nowadays a great deal of this bother and worry to artist and model alike is obviated.

I should be obliged to Mr. Barrett if he would say in what way a portrait painter may avoid or shorten the sittings nowadays.—I am, yours, &c., Liverpool, July 9, 1887. A PAINTER.

Exchange Column.

* * No charge is made for inserting Exchanges of Apparatus in this column: but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Binial lantern and object slides for microscope. Cash adjustments.—Address, W. I. CHADWICK, Brooklands, Manchester.

Will exchange one of Rouch's patent whole-plate cameras, with one double dark slide with waterproof case, for Universal studio camera, same size, with dark slides.—Address, W. C. BASSZET, care of H. Butler, 127, Eastgate, Rochester.

12x10 Mangle portrait lens, 14x11 studio camera, two slides, and table stand, plain cloth, and outdoor background, for exchange. Wanted, a portable camera and lens. Difference adjusted.—Address, C. HEWITT, Photographer, Weymouth.

Silver close-curb Albert guard, weighs over four and a half ounces, locket to match, exchanged for good rapid rectilinear lens, short focus, or good cabinet lens, or photographic accessories.—Address, HORTON, Photographer, Caroline-street, Cardiff.

Wanted, quarter-plate camera, with three or more double backs, and rapid symmetrical lens, by good makers, in exchange for watertight cases and baths, 15x12, two 12x9, and 8x5½, and head-rest by Johnston.—Address, R. HENDERSON, Station-street, Keswick.

Modern camera, by Hare, 7½x5, with six double backs, waterproof case, Dallmeyer's lenses; also quarter-plate camera, by Meagher, with eight double backs, lenses, tripods, &c.; in exchange for microscope. Cash adjustments.—Address, W. I. CHADWICK, Brooklands, Manchester.

Photographer's dark room on two wheels, so built that you can be at work in two minutes on the roadside or anywhere, carries cameras and everything inside, built by coachmaker, cost £7 10s. Will exchange for whole-plate portable bellows camera and group lens; must have two double slides.—Address, W. J. Waterloopromenade, Forest-road, Nottingham.

I will exchange a Grubb's 22 portrait lens (four inches diameter) for 10x8 portraits, cost £16, for a good 10x8 or whole-plate portable camera; also a half-plate camera, with all improvements, fitted with three double backs, Ross' rapid symmetrical lens, Piacini pneumatic shutter, all in case complete, for a Ross' cabinet lens.—Address, W. T. WHETTER, Photographer, Villiers-road, Bristol.

Answers to Correspondents.

S. A. J.—Sulphide of potassium and "liver of sulphur" are one and the same thing.

C. M. ROBERTSON (Liverpool).—Thanks for suggestion, which we shall probably adopt.

J. LOWE.—The simplest method of making carbon prints on opal glass is to develop direct upon the glass, using a reversed negative.

NEMO.—Paraffine wax is far better for tining a wooden bath which is to contain silver solution than pitch. It may be applied in a similar way.

W. H. H.—Messrs. Sprague & Co. have not published the process by which they produce their "ink photographs," consequently there is no work on the process.

G. BROOKLY.—Unless you require a lens for photographing in very confined situations, by all means choose the lens of the rapid type. It will be far more useful for general purposes.

S. S.—There must be some error in your formula, as fifteen grains of gallic acid cannot be dissolved in an ounce of water. About three or four grains per ounce is all that can be got into solution.

EXPOSED.—Immerse the plates in a solution of bichromate of potash, and well wash. They can then be used again. Unless the whole of the bichromate be eliminated the plates will prove very slow.

A. T. S. BERRINGTON.—We believe the Detective camera we described to be the same as that referred to in the leaf you enclose. It had no lens when received, which explains the Wray lens having been fitted to it.

LUKE J. HEALY.—If you can make zinc surface blocks for working along with type it will prove a valuable acquisition. There are only a few manuals devoted to the subject; Wilkinson's is in the English language, and it is one of the most practical. If you varnish the crayons you will spoil them.

N. B. J. writes: "I should be very much obliged if you would, through the 'Answers to Correspondents,' inform me if you consider carbonate of ammonia has advantages over other alkalies for the pyrogallic development of instantaneous work. I have seen it recommended as a good slow developer, giving plenty of density."—Carbonate of ammonia possesses no advantage over any of the other alkalies, and it is very seldom used for any class of work.

DESMOND HILL.—The size of any subject included in a plate is determined by the focal length of the lens. In your case it may be advisable to have another lens in addition to the present one. The focus that we would suggest for this additional one would be nearly twice that of the other. And, by the way, to assist you in arriving at a conclusion, remove the front lens of your present combination, and see what sort of image as regards dimensions you get with the back one when employed alone. Of course, the camera will have to be expanded very considerably.

J. H. COWARD.—The stripping of the film of an ordinary gelatine negative is a somewhat risky operation unless the glass was specially prepared for the purpose before the emulsion was applied. However, you may proceed as follows:—Place the negative on a levelling stand and pour on a solution of gelatine containing a small proportion of glycerine; allow it to set, then rear the plate up to dry. When the film is perfectly dry, and not before, pass a knife round the edge of the plate and carefully strip. In America and Germany plates prepared specially for stripping are articles of commerce.

A. ELLIS writes as follows: "Having intensified a negative about three months ago with Edwards's intensifier, and taking it up lately to print from, it appeared to be weaker than it was at first, so I determined to make a fresh one by taking a transparency by contact from which to get the new one. With this intention I exposed a plate and developed, but instead of getting a transparency, as I expected, a negative exactly similar to the other was the result. I may mention an inch margin was painted on with 'Bates's black,' which with the other dark parts came out dark. If you will kindly tell me the cause of this, and whether it is of frequent occurrence, you will oblige me."—The cause of the apparent, to our correspondent, phenomenon, is that the plate was very much over exposed, and this produced a reversing action of the light. There is nothing uncommon in the matter; indeed, this property of the reverse action of light is utilised by some for producing reversed negatives for the photo-mechanical process.

JOSHUA RILEY says: "I have met with a stubborn case as regards removing the colour or stain from a local spot or place on a 12×10 negative. I thought it very likely your varied experience might aid me in succeeding in doing so, as the negative is one I want to make use of, and at present with this colour it prints too hard on the spot to be of any service. 'How the local colourisation was produced.' The negative was developed with pyro and ammonia, alumed, and fixed as usual, also washed; when, finding the place marked too dense, I thought I would try cyanide; so took a piece of cotton wool, dipped it into a solution of cyanide, and rubbed the place with the cotton wool, which caused the colour to change into a still more non-actinic colour. Can you suggest anything that would remove it?"—In the print enclosed the portions marked as being stained agree closely with the denser parts at one end of the negative, leaving perfectly clear, as we presume, the adjacent transparent shadows. Had the stain encroached upon the shadows, we should have attributed it to imperfect washing, but as it appears only in denser portions of the image this cannot be the case. Perhaps some of our readers can suggest a remedy.

A. L. (New Zealand) writes: "Will you kindly, in your 'Answers to Correspondents,' reply to following queries by numbers:—1. Is a condenser necessary for enlarging, using the lens and camera in which the negative to be enlarged was originally taken, either by daylight or artificial light?—2. What is the most convenient form of using magnesium wire to light a room for photographing by night?—3. Where is Coventry's emulsion pourer to be procured?—4. I see coal-tar varnish mentioned in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC; how is it made?—5. What is the cause of want of definition in bromide prints (by contact) and bad colour?—6. Have you any objection to state whose plates you consider best for pure landscape work? I know you object to recommend any maker, but I am not able to get a trial sample and judge for myself, and it is rather rough to get out a gross of plates and find them unsuitable. As for the goods supplied by local stores, it is not doing justice to the manufacturers to use them, as in many cases they have been damaged out here."—In reply: 1. In working by daylight a condenser is not required, but with artificial light one is desirable.—2. The most convenient plan is to employ one of the lamps sold for the purpose. Mr. Solomon, of Red Lion-square, has a very convenient form, so has Mr. Hart, of Kingsland-green.—3. We have not heard of the article for some time.—4. Brunswick black, as sold at the oilshops, answers the same purpose and is far more pleasant to use, and also saves the messy operation of making. Use it in preference to the other.—5. There should be no want of definition. The bad colour is, no doubt, due to under exposure and long development.—6. We regret that we cannot comply with your wishes. The plates by all the makers you name are good.

ERRON in paper on *Metric Measurements*. For the word "variety," eleventh line, read "vanity."

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting, July 27, 1887, will be on *Photographing Flowers*. Saturday outing, Richmond. Meet at Metropolitan Station, Richmond, at half-past two.

CONVENTION NEGATIVES.—Mr. Keene, of Derby, writes:—"The Convention I consider a great success, and I am well pleased with the few negatives already developed. I shall want to take my camera to Scotland again."

J. LILBURN ROSHER, Châlet Rose, Bex, Switzerland, writes: "If you know any one passing through here this summer, I should be glad to see them and give them the use of my dark room and chemicals, as there is no photographer in the town."

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The usual monthly technical meeting of this Society will take place on Tuesday next, July 26, at eight p.m., at the Gallery, 5A, Pall Mall East. Open at seven p.m. for journals and conversation.

THOSE photographers who desire to secure most charming effects of water-falls without leaving London should visit "Arcadia" in the Agricultural Hall, and bring with them their detective cameras. Mr. Harry Etherington has made of it a most attractive place.

MEDAL AWARD.—We are pleased to learn that Mr. W. Clement Williams, the Hon. Secretary of the Halifax Photographic Club, has been awarded a silver medal of the first class for an exhibit at the International Photographic Exhibition of Italy held at Florence.

FROM Mr. John Gray, B.Sc., we have received a portrait of himself in three degrees of amplification, if we may so term it. A large head is attached to a smaller body, and these are perched upon a still smaller donkey-cart. J. Downey & Sons, South Shields, are the artists.

GETTING THE FOCUS.—One of the "convened" photographers observed last week that, "while photography used to be considered the Cinderella of all the arts and sciences, he thought it was going to take its proper place now." "And why," asks Asinus, who is nothing if not classical, "should not photography still be considered a Cinderella? Is not Cinderella indissolubly associated with the hearth, and is not the Latin for hearth *focus*? Hee-haw!"—*The Bailie*.

AMONG several fine photographs obtained of the groups formed during the various excursions at the Convention, some admirable ones of large dimensions and singular clearness, taken by Mr. John Stuart, of Glasgow, and some lovely platinotypes of smaller dimensions, by Mr. R. Keene, of Derby, were exhibited at the last meeting of the North London Photographic Society on Tuesday by the President of that body. It need not be said that they were examined with great interest.

PHOTOGRAPHIC EXHIBITION IN DUBLIN.—There is to be a Photographic Exhibition in Dublin next October. "Through the kindness of the Academicians," writes Mr. Greenwood Pym, the Hon. Secretary, "we have again secured the splendid galleries of the Royal Hibernian Academy of Arts, second to none for a picture exhibition. We expect to be able to make such arrangements as to carriage as will reduce the cost of this item to exhibitors to almost a nominal sum. There will be a most liberal prize list, details of which, as well as other particulars, will be supplied on application."

CAMERA CLUB.—Excursion (for members and friends) to Pangbourne, &c., Saturday, July 23, 1887. Train from Paddington at twenty-five minutes past ten a.m., arriving at Pangbourne at forty-three minutes past eleven. Later train, for those joining in the afternoon, at five minutes past one p.m., arriving at twenty-eight minutes past two. The London and South-Western from Waterloo can be taken to Reading and a change there effected to the Great Western, but the trains do not fit in well. There are bathing facilities at Pangbourne at all times of the day. Apply to lock-keeper. Dinner at the "George" Hotel, Pangbourne, at fifteen minutes past six p.m., in time to catch the return train to Paddington at fifty-two minutes past seven p.m.

G. B. BRADSHAW & Co., of Altrincham, Cheshire, write: "In your issue of July 1 of THE BRITISH JOURNAL OF PHOTOGRAPHY, and touching upon exhibits at the Manchester Exhibition, we note you say you are left in doubt as to whether the exhibitor was the producer of the enlargement before you. This would be easily accounted for if the other exhibitors have been treated in a similar manner to ourselves. We have four very fine enlargements hung, one of Sir W. C. Brooks and Lady Brooks, over five feet, and three others not so large (altogether covering fifty square feet), for which we had made four wood tablets designed to suit pictures. We followed the Committee's instructions as to colour of ground, lettering, &c., and screwed them on, so that they did not hang outside our own frames, and they simply bore the name of the subject, and stated that they were photographed, enlarged, and finished by us on our own premises; but the Hanging Committee would not allow them to remain on, and, in spite of our entreaties and protestations, they were roughly forced off, in doing which they injured the frames, and changed their positions several times. They damaged the ornamental frames to such an extent that they are now scarcely fit to exhibit."

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1421. VOL. XXXIV.—JULY 29, 1887.

THE BEST MODE OF BACKING PLATES.

In our last remarks upon this subject we briefly touched upon what might be termed the three typical modes of backing plates that have, by one practitioner or another, been recommended—black varnish (that is, solution of asphalte), coloured collodion, and a powder pigment made into a paint. Since then, as will be seen in our last, a correspondent who finds the value of backing to his plates has written to advocate the use of bitumen dissolved in benzole. We entirely coincide with him as to the advantages of bitumen, but we cannot avoid the conclusion that if the systematic use of a backing entailed the employment of a benzole varnish, and the ultimate removal of the coating by scraping, the adoption of this ail to good work would be the exception and not the rule. Now, with plates as at present made, we should hope eventually to see few photographers disregarding its use. We are raising objections not to the effects of this coating, but merely to the practical side of the question, and as our whole purpose is to give descriptions of methods involving the least amount of extra labour or expenditure of time, we dismissed solutions of benzole from the range of practical photographs.

There then remains collodion *versus* paint. The first question to be solved was, Had one of the two any practical advantage over the other? Our method of trial was as follows:—Placing the camera at one end of a long room we arranged a swinging mirror on the floor at the other end, so as to send into the camera the reflection of a bright part of the sky seen through the window; one-half of this reflection we shut off by fastening across the mirror a piece of black velvet. The camera image then consisted of a dead black in immediate juxtaposition with bright sky, the latter being also crossed by the sash bars. As a test object this was better than selecting an ordinary interior with distant window, the velvet offering the best possible medium for exhibiting halation if it existed. We then coated plates of varying degrees of density over one-half of their back surfaces with the various backings under experiment, and gave equal exposures to each side of the partially backed plates, while the unbacked plates were tried against one another.

The results were sufficiently striking. Of the uncoated plates, those with thin films not only rendered the black velvet as a mass of deep grey fog, with the sash bars hardly visible, but the whole plate exhibited a slight haze, palpably demonstrating the worthlessness of the particular plate, and, we should say, of its class, for all subjects including bright objects. With plates possessing a thick rich film the results

were far superior; but still the sash bars were deeply clouded, and grey fog covered the velvet.

When, however, the plates with coated backs were tested, the difference was extreme: the thinnest plate so treated gave results infinitely superior to the thickest of the unbacked plates. Next testing backing against backing, we found that the best of the pigment backings were decidedly superior to the collodionised plates, and thus economy and usefulness were combined. As to the plates among themselves when coated with the best backing there were distinct differences. The thick yellow films (the exposures being long enough in all cases to enable all the furniture in the room to be well brought out) gave the greater portion of the velvet with scarcely a perceptible stain or fog, except close to the light, and there a faintly visible band of fog could be seen upon close scrutiny. The thin plates were not entirely free from fog over the whole of the velvet, thus showing that either our backing was not theoretically perfect or that some of the other fog-exciting causes, referred to in our first article on this subject, were at work.

The plates of medium density gave very fair results, but it could not be said that the velvet was a perfect representation of a black surface.

The backing we employed and found best was a paint made of ivory black and water, held together with a sufficiency of gum arabic solution to cause the paint to exhibit a semi-glossy appearance when dry. Gum was chosen on account of its index of refraction being little removed from that of glass, and we found that if too small a quantity were employed the true action of the backing did not come into play. The colour of rich velvety black, as shown through a sample piece of plain glass, gave way to a more grey tone when the paint was quite dry, and the reflection of a bright object upon it was seen to be distinctly duplicate, though the brightness of the second image was much less conspicuous than was seen with a piece of unpainted glass. It is quite evident that the old experimenters who used lampblack, or other pigment, and water, though they had discovered the cause, and indeed the cure, of halation, yet failed to adopt a really good mode of carrying out the teaching of their discoveries.

In making all these experiments it will naturally be seen that we had a large number of plates to prepare, and it was during the development that we formed the strong opinion against asphalte coated plates above recorded, even the gummy paint with water being troublesome enough to get rid of. In the actual routine of development in a large establishment or in

the home work of an amateur with a kit full of exposed plates, we could see what a drawback this removal of the backing would be, and we endeavoured to devise a method which involved the least outlay of time in getting rid of it. This we achieved by the simple expedient of stirring a little glycerine into the above described paint, the result being that, although the backing dried, in a sense, it was yet so soft that when water was turned upon it the whole coating softened directly and was washed away without difficulty.

The actual formula, then, for the paint that we found most effectual and thoroughly easy of removal stood as follows:—Gum arabic was dissolved in water in the proportion of an ounce of gum to six ounces of water, and for each ounce of gum used an ounce of glycerine was added. In practice we kept a stock of gum dissolved in water—one gum to two water—and we diluted the glycerine with its due proportion of water and then added it to the gum solution. If this were not done and the glycerine were added at once to the gum solution it was apt to cause clots. This gum-arabic-glycerine-water mixture was then used to mix with the powder paint purchased at the oil and colour shops, using a flat knife to work it into a thick cream, a large plate of glass doing duty for the painters' slab. Finally, to ensure an even mixture, the whole was squeezed through muslin into an earthenware vessel. The paint was laid on the back of the plate with a broad camel-hair brush, and a few dozen plates could be coated and reared up to dry in a very short time, while for removing the coating before development a slight rub with the fingers under a stream of water from the tap rapidly dissipated every particle of pigment.

In conclusion, we would in the strongest manner possible express our sense of the extreme value under almost all circumstances of a suitable backing to gelatino-bromide dry plates, and we hope that our remarks may be the means of drawing more attention to this important development of practice.

AMATEURS AND RETOUCHING.

ONE of the most interesting papers for the amateur read at the recent Convention at Glasgow, was that by Mr. T. N. Armstrong on *Home Portraiture*. For many years portraiture has been to the amateur a practically unworked field, not that amateurs did not attempt portraiture—for who is not too well acquainted with the miserable work in that line that generally represented the earlier efforts of the tyro?—but simply because none but the wealthier, who could afford to erect a portrait studio, were in a position to cope with the difficulties of lighting.

With the advent of gelatine plates, however, the necessity for the old glass room, with its flood of light from top, front, and side, ceased, and so far from the conventional "studio" being an advantage, it is a question at the present day whether the reverse is not the case. The system of lighting adopted by most of the leading portrait photographers of to-day differs essentially from that in vogue in the days of wet collodion, partaking more of the character of the illumination of an ordinary room or of a portrait painter's studio. Indeed, we heard a well-known leading professional photographer declare some years ago that if he were building a new portrait studio he would have no lights but the side windows, and, in fact, would prefer an ordinary room for the purpose if the windows were high enough.

That successful portraiture can be executed outside the

glass house, and without special preparations or accessories, is amply proved by those professional portraitists who make a practice of taking "home photographs." In such cases the operator, with his apparatus and plates, presents himself at the residence of his sitter, and, availing himself of circumstances as they exist, makes the best he can of the job. How far success rewards him is shown by the numerous exhibits in this class of portraiture that have been seen in recent exhibitions and elsewhere, many of which are fully equal to the best work executed in the studio.

We can, therefore, cordially agree with every word that Mr. Armstrong says in encouragement of the practice of "home portraiture" by amateurs, feeling convinced that if they devote but a moderate amount of study and attention to the subject they will be amply rewarded in the pleasure afforded both to themselves and their friends. There is an undoubted predilection in favour of portraits which do not proceed from the ordinary professional studio, even though they do not possess the conventional gloss and finish; the mediocre production of an amateur friend will frequently be valued more highly than the really first-class work of the professional simply because "it is so natural." How much more, then, will amateur work be valued if, in addition to the ordinary qualities, fancied or real, attributed to it, it possess also some, if not all, of the artistic finish of the professional.

In recommending the practice of retouching, Mr. Armstrong, therefore, makes a step in the right direction; but in our estimation he errs a little in attaching such prime importance to it. He implies—nay, says in so many words—that until he took lessons in and mastered retouching his portrait work was a miserable failure. Now this is calculated to deter many amateurs, and especially those who aim at turning out only good work, from attempting what appears a hopeless task. How many amateurs have the time, even if they possess the natural capacity, to become proficient in retouching? Retouching is as much a study, and requires as much deep attention, as drawing or painting in the mastery of even the manipulatory details, and a man may be an accomplished and even artistic photographer without possessing in the slightest degree the necessary manipulatory faculty to successfully retouch.

Even suppose he possess the merely mechanical capability of applying the lead to the negative film in a smooth and even manner, his knowledge of anatomy and expression may fail him, and without that knowledge we all know how extremely easy it is to entirely destroy a likeness or alter an expression. Here, then, is taken away at a sweep one of the chief charms of an amateur "home photograph"—its "naturalness" or its likeness to the original.

But, after all, we cannot help thinking that Mr. Armstrong has unnecessarily condemned his untouched work. We have seen a great amount of home portraiture by amateurs that has been entirely untouched so far as the negative is concerned, but which if printed, finished, and burnished with all the care of the professional, would compare favourably with a large proportion of the latter class of work. There will, of course, be instances where retouching may be necessary, as in cases of under exposure, or where errors in lighting have been made, but, as a rule, our counsel to amateurs would be to meddle with the negative as little as possible, no more, in fact, than is required to remove defects, unless they are fairly proficient with both pencil and brush. With the aid of simple screens and reflectors only, and such lighting devices as Mr. Armstrong

mentions in his paper, the amateur portraitist will find himself in a position to turn out remarkably good work "at home."

IN connection with the Convention excursion to Edinburgh, Mr. J. M. Turnbull, of that city, informs us that he and others of the brotherhood there have received several letters from the visitors, thanking them for their reception. "But," says Mr. Turnbull, "you may assure them from me that we here think ourselves highly honoured by their visit, and that the indebtedness is on our part, not on theirs." Our own opinion is that friendly intercourse of this nature acts most powerfully in cementing and strengthening the friendship and good feeling previously existing among the fraternity of different—*nationalities*, we were going to say, but "*citizenships*" better expresses the idea. Anyhow, Edinburgh acted right royally on the occasion referred to.

ON more than one occasion we have directed attention to the advantage, in a pecuniary sense, that would probably accrue to photographers at seaside places and other holiday resorts, by their being provided with backgrounds depicting picturesque spots or places of interest in the locality, before which sitters could be posed in the studio. Portraits taken with backgrounds of local scenery would possess considerable interest, as they would always serve as a memento of the visit to that particular place. At most spots of interest which are much frequented by visitors, one usually finds an itinerant photographer located ready to take photographs of them. As a rule, the productions of these itinerants are not of very high order, and they are generally ferrotypes or glass positives. Moreover, owing to the portraits being taken out of doors, and often unavoidably with the sun full on the face, the likeness, however well the work may otherwise be executed, is seldom satisfactory. But if the portrait were taken in a studio, with a judiciously made up background representing a local scene, an interesting picture as well as a pleasing likeness would be secured. We are fully aware that some artists are provided with such backgrounds, but they are not nearly so general as might be imagined, and few make a speciality of them.

IT is not necessary when a portrait is produced in the studio with a scenic background that the latter should be a painted one, for it may be introduced by a second printing from a negative direct from nature. The simple method introduced many years ago by Mr. Edge, of Llandudno, is well adapted to the purpose. Mr. Edge's plan is this: The portrait negative is taken in the studio with a white—or rather, a very light—background, so that when it is printed the figure appears on a plain and slightly toned paper. The figure is then painted over with some non-actinic water colour—*gambo*, for example—so as to protect it from light in the second printing. When the colour is dry, the print is exposed behind the landscape negative, care being taken that it is not deeply printed. In washing the prints prior to toning the colour is removed, leaving the paper perfectly clean. It may be explained that the view negative should be of a very weak and delicate character, otherwise the background will appear obtrusive, and thus spoil the artistic effect. The slight tone which the background has before the landscape is printed softens the effect, and gives atmosphere to the picture. A variety of these thin negatives of local scenery could easily be produced and kept in stock ready for use as required. If this were done, sitters could make a selection of the views they preferred as backgrounds for their portraits. Photographers would also be saved the trouble or expense of making the painted backgrounds.

AS on the occasion of the Jubilee rejoicings in London and the *fêtes* in the provincial towns, so were photographers—amateur and professional—busy at the naval review at Spithead last week. Some excellent negatives of the event have been secured. These pictures will, of course, be valuable as interesting mementoes of the review. Some of the pictures, we are informed, are somewhat marred by the smoke. In some instances, however, when the camera was to the windward, the smoke and steam have enhanced the effect.

THERE is very little probability of the long-promised Copyright Bill being dealt with this session. However, photographers will do well to be on the alert, and enter into some sort of combination, as we have several times suggested, to watch over their interests in the matter. Although several M.P.'s are, we are told, enthusiastic amateurs, it must be borne in mind that the framers of all the Bills hitherto brought before Parliament are by no means favourably disposed towards photography and photographers. In all the Bills which have been introduced there has been a very stringent clause with reference to the photographer using the negative for any purpose whatever, except to the order of the sitter. If this clause becomes law, enlargements made on speculation, and the exhibition of portraits as specimens without the sanction of the sitters, will be things of the past. Sooner or later, a new Act on Copyright will be passed. When this is done, it will be useless for the profession to complain if it proves inimical to their interests. By the way, this would have formed a good subject for consideration at the recent Convention, seeing it is treated with apathy by the Photographic Society of Great Britain.

COMPLAINTS on the part of the public are very strong as regards the fugitiveness of photographs. One thing appears pretty certain, namely, that the general run of silver prints issued by professional photographers at the present time are of a less permanent character than were those produced twenty years ago. Feeble negatives and lightly sensitised paper have, we surmise, much to answer for in this matter. Long soaking in water, particularly at this season, does not conduce to permanency, and therefore should be avoided. When prints are allowed to soak in water for a long time—twelve or fourteen hours, for instance—and the temperature is high, the brilliancy of the prints is usually more or less degraded. If they are left in water for a still longer period, as is sometimes done, incipient fading, yellowness, and spots, are frequently observable when the prints are finished.

AN evening contemporary says:—

"The owners of the faces portrayed in the *Pall Mall Gazette* yesterday, can scarcely have been flattered by their so-called portraits which appeared in that journal. Except Mr. Newton—and his is but a distant resemblance to himself—the rest of the faces might serve for any one, from Adam to Cleopatra. A man's face is, we suppose, not his private property; but if it is taken from him it might be, at least, treated with politeness."

With regard to the likenesses in question, we can but endorse our contemporary's opinion. The plan usually adopted for this kind of illustration is to make a bold sketch from a photograph on a larger scale, then to take a negative of it the size required, and from that produce a transfer on zinc, and then etch in the ordinary way. Of course the likeness, under these circumstances, is dependent upon the skill of the draughtsman who copies the original photograph. Some of these type blocks are produced in a couple of hours or so, the electric light being used for making the negative as well as printing the transfer. A good, cheap, and expeditious method of producing phototypic blocks in half tone, which can be worked in an ordinary newspaper machine with type, is yet a *desideratum*.

INTENSIFICATION.

MR. HENDERSON's remarks in the discussion on my paper read before the late Convention afford me an opportunity of supplying an omission which occurred in the hurry of writing. As Mr. Henderson pointed out, the application of the solution of alum and hydrochloric acid to a plate that has been intensified with silver would have a tendency to form chloride of silver in the film. This is precisely what is required, but the omission consisted in not directing the subsequent use of hypo—a second fixing operation, in fact. I have not the reference by me as I write, but I think this has been more than once mentioned in the pages of the JOURNAL when the subject of silver intensification has been on the *tapis*.

With regard to the possible effect of any chloride of silver so formed if left in the film, I am not inclined to think it would prove

very dangerous, the actual quantity being so infinitesimal. I have never intentionally made the experiment of testing the stability of a negative in which the minute trace of chloride has been allowed to remain, but it is very possible that amongst the silver intensified negatives in my possession there may be some in connection with which the second fixing operation has been neglected; still, I have noticed none that show any signs of discolouration so long as they have received the acid and alum treatment.

As a matter of fact, the quantity of silver remaining in a gelatine film after intensification and washing—other than that actually forming the image—is so infinitesimally small that its conversion into chloride produces no visible effect, and any change that may take place in that minute—nay, invisible—quantity of the haloid under the action of light, may, I think, be awaited with tolerable equanimity.

Not so, however, if the silver be *not* converted into chloride. All who have worked with gelatine emulsions or gelatine printing processes in which silver is the sensitising agent, are aware how tenaciously gelatine and free, or soluble, silver salts cling together. Whatever may be the nature of the combination, it is found practically impossible to remove silver nitrate from gelatine with which it has been in contact by mere washing. In like manner it is impossible to wash off the effects of contact with silver solutions from the hands or linen, even though water be copiously applied at once and before any sign of stain has appeared. In time, and especially on exposure to light, the inevitable stain will appear, from which it would seem that some insoluble organic compound of silver is formed.

If such be really the case, the proportion of silver in the compound must be small and the bond of union between it and the organic matter extremely feeble, for the application of a weak solution of a soluble haloid effectually prevents any subsequent discolouration, and in the case of a thorough preliminary washing the quantity of silver haloid formed is insufficient to produce any appreciable discolouration upon subsequent exposure to light. The difference in the colourific powers of the organic and haloid silver compounds is, in fact, most remarkable, and it is in order to counteract the strong tendency in this direction of the former, by converting it into the latter, that the alum and hydrochloric acid are applied to an intensified film.

In the early days of gelatine emulsion photography, it was by no means unusual to meet with formulæ in which the emulsion, previous to washing, contained an excess of silver nitrate—a state of affairs entirely unknown at the present day. The reason of the relinquishment of the excess of silver was not so much that emulsions so made would not work well, as that they were found not to keep—or rather that the dried films would not keep. I remember several years ago, at a meeting of the Photographic Society, Mr. Herbert B. Berkeley exhibited a number of negatives and unexposed plates bearing directly on this question. The emulsion had been made with excess of silver, and the plates when newly prepared gave unexceptionable results, as was proved by the sample negatives handed round. But upon opening a packet of the same plates, after keeping with all care for a few months, they were found to have developed, spontaneously, a deep red stain, and to be wholly useless for photographic purposes.

At that time I made some experiments upon gelatine films which had contained free silver, the latter being washed out as perfectly as possible. Plates coated with emulsion and also with plain gelatine solution so treated, were dried and a portion of their surfaces then soaked in a five per cent. solution of potassium bromide, the whole again well washed and redried. In the result, after keeping carefully wrapped up for some months, protected from light and damp, all such plates were found to be more or less discoloured in those portions not treated with potassium bromide. The plain gelatine films exhibited a clear stain, varying from a yellowish to a brownish red, the parts treated with bromide remaining perfectly colourless and transparent.

For these and other reasons I do not anticipate that the omission of the second fixing operation is likely to cause a great amount of trouble, though under some circumstances, as for instance a prolonged or forced intensification, a sufficient quantity of silver might be left in the film to produce a visible veil when the plate is placed in alum and acid. In such a case the second fixing would be imperative.

In conclusion, it is possible that objection may be taken to the second fixing operation and its concomitant troubles of washing, &c. To reduce these troubles to a minimum, I would suggest the replace-

ment of hypo by sulphite of soda in strong solution, as proposed by Captain Abney. The lower solvent power of the sulphite as compared with hypo would be of little moment in the presence of so small a quantity of chloride of silver, while the comparative harmlessness of the silver products, and the absence of dangerous reactions with the alum and acid, would prove advantageous in reducing the trouble involved in the different washings.

The latter trouble might probably be still further minimised by combining alum, chloride of sodium, and the sulphite in a single bath for application after intensification.

W. B. BOLTON.

CONVENTION JOTTINGS.—IV.

(From our Special Correspondent.)

THE Thursday's trip was by the "Columba," sailing down the Clyde, through the Kyles of Bute, as far as Tarbert, where it was arranged Mr. John Stuart would take the Convention group during the two hours' stay there. When we got up in the morning it was drizzling and wet, and the outlook for a good day was anything but propitious. Many of the party went down all the way by boat, and others took train an hour later for Prince's Pier, in time to catch us up at that point. By the time that they boarded us the sky had cleared a bit and things looked more hopeful.

When we reached Rothesay, an hour later, the sun was out in all its glory, and so were the cameras—which seemed to have hung fire up till then. The wet morning had kept back many of the regular tourists, and our company had pretty much the run of the boat. Cameras could be seen about everywhere, from 15 × 12 size down to one as small as an ordinary watch. The detective element was in great force, and shots were being fired at every little knot of people on board, so that many recollections of the day were carried away, the success of which will depend on future development. When we arrived at Tarbert, we all gathered together at the large rock near the mouth of the harbour to have the Convention group taken by Mr. John Stuart, and when we got all in mass there really was some doubt regarding who was the manager of the posing of the picture, suggestions were so many and varied; but Mr. Stuart quietly waited till the fizz subsided, and then he had everything his own way. Cameras big and little to the number of twenty or thirty were ranged along either side of Mr. Stuart's big one, and all got a chance of a shot before the company separated—so that there should be no lack of groups of the Convention this year.

Then came the scamper over the shore in all directions to fill up the time left, photographing little bits each on his own account.

Mr. Sail, from Belfast, was kindly informed by a young native that the roads would be found fine and level for his machine; he evidently thought it was a bicycle.

On the return journey some highly successful groups were taken on board the "Columba." After a very enjoyable day, the company reached Glasgow in good time for the evening meeting.

The trip to Edinburgh took place the following day, Friday, and of all the excursions for which the Glasgow Convention will be famed, that to Edinburgh deserves special notice. From fifty to sixty of our members found themselves at the railway station in the morning *en route* for the Modern Athens, escorted thereto by some of the Glasgow brethren whose avocations did not permit of their accompanying the party on this occasion. Special carriages had been attached to the train for the party, and in due course we were whirling eastward at express speed. Of the fun that took place on the journey it were superfluous to speak: given a large party of photographers on pleasure bent and in the most boisterous of spirits, a calm, sunshiny day, rushing along through a lovely country at forty miles an hour, and you can well understand the rest.

A wag in our particular carriage undertook to point out the historic scenes through which we were passing, and (for this occasion only) imported into the vicinity of the track localities famous in the national history. "Here," he exclaimed, pointing to a rivulet, "is the Till, and on yonder field adjoining was fought the disastrous battle of Flodden, at which Sir William Wallace routed the forces of Percy of Northumberland." A turnip field near Falkirk served in like manner to do duty for the field of Bannockburn, from an adjoining height backing which "King James did rushing come." Even Ben

Nevis was, for this special occasion only, brought into the scene among the Pentlands on our south. What with veritable Scottish history of this kind, "Nap," discussions on photography and everything else, the time passed so pleasantly that the old-time cry of "Bonnie Edinburgh, I smell ye noo!" was received as a joke, which was, however, dispelled by the appearance of Donaldson's Hospital and the phalanxes of solid stone houses which usher in the Modern Athens from the western approach.

On our arrival at the Waverley Station we had a right royal welcome from several gentlemen, representatives of the Edinburgh Society, who were waiting to receive us, including Messrs. W. Forgan, C. Fraser, W. Crooke, J. Crichton, G. G. Mitchell, W. T. Bashford, J. M. Turnbull, and T. Wandale. Brakes were in attendance, and our friendly conductors embarked us at once, and away we drove over the most beautiful of cities. The Calton Hill was the first point of interest we visited, the view from which is magnificent—but Edinburgh is highly favoured with spots of vantage-ground rising every here and there from which all its beauties may be seen and admired.

We then went on to the Castle by Princes-street. When at the Castle Mr. Millington secured a fine negative of Andrew Carnegie sitting in his carriage. This was a fortunate shot, for it was taken at the time when Mr. Carnegie was enjoying the honour of the freedom of the City of Edinburgh, which the citizens had conferred upon him as some slight acknowledgment of their gratitude for the £50,000 he had gifted to Edinburgh to institute a free library in the city. From the Castle we drove down the Castle Hill, High-street, and some of the older parts of the city, whose old and broken walls breathe history. Some photography was done at the White Horse-cloze which was both interesting and amusing. Holyrood Palace was our next halting-place, after which we drove round the Queen's Park to Craigmillar Castle, where a sumptuous repast was served up by our Edinburgh friends, spread out picnic fashion, and, oh! didn't we enjoy it! J. T. Taylor proposed prosperity to the Edinburgh Photographic Society, and, dating back, he told them he remembered when it was very young indeed—he nursed it when a baby. Mr. W. Forgan replied for the Edinburgh Society, and expressed his pleasure at the success of the Convention. Then came the taking of the group by Mr. W. Crooke, who telegraphed to the Convention meeting the same evening that it had turned out all right.

During the day Mr. J. T. Taylor, and subsequently Mr. Henderson, of London, and Mr. J. Henderson, of Perth, paid a hurried visit to the veteran photographer, James G. Tunny, now lying waiting, it is to be greatly feared, the approach of the last messenger. Mr. Taylor, in subsequently speaking of this visit, said, "I found the giant prostrate in bed, paralysed from the chest downwards. He was evidently suffering great pain, but his eyes sparkled brightly when I told him of the Convention doings of the four days previous. Well I knew that of all the kind-hearted Edinburgh men whom I had that morning met, he, a member of the Convention Council, would have been the very foremost to give us welcome to the Old Dundee but for his terrible affliction. After a brief time spent in converse we parted, each feeling that he would see the other no more. My acquaintance with this father of practical photography in Scotland dates from over a quarter of a century ago, and, taking him all in all, Tunny is a man whose like we ne'er shall look upon again."

After leaving Craigmillar Castle we drove through the meadows, on the ground of which the very successful Exhibition of last year was erected, thence by the Lothian-road, Charlotte-square, and George-street. We reached the Waverley Station, where, after many partings, we returned to Glasgow, having spent a day long to be remembered as one brimful of pleasure.

The Friday evening's meeting was full of work. After a very interesting paper on *Modern Film Photography* by Mr. B. Wollaston the tag ends of business and discussion were drawn together to bring matters to a close, this being the last night of open meeting. When nine o'clock rang out we all adjourned to the "Bath Hotel," where dinner was set for the members, who, as they sat round the table, looked, one and all, as if they had come to enjoy themselves. The chair was taken by Mr. John Stuart. Mr. W. Lang and Mr. J. T. Taylor acted as Vice-Presidents on the occasion. After the toasts of "The Queen," "The Amateurs," "The Profession," and "The Convention," we en-

joyed three hours of mirth and fun filled in with song and story. The time passed like an instantaneous exposure, and one wondered how it had gone.

On Saturday morning the Council met at Cranston's "Waverley" to bring the business of this very successful Convention to a close. At the meeting fourteen names were added to the Council—and with regard to this there have been some questions raised about the sizes of Committees and Councils, and quite an unnecessary sneering at the largeness of the same. It can be well understood that this carping is made by those who are not in a position to know anything about the matter, never having done any work for the Convention from the very first. The only thing they seem able to do is to sit and tell us it is all wrong. With some people everything is all wrong always. These are the sort of folk who, when they go to heaven, will catch cold passing through the clouds, and will insist, when they get there, that their "haloes" don't fit.

As a matter of fact the very magnitude of the local committee at Glasgow was the groundwork of the great success of the meeting, for the larger proportion of them were working members, and not names merely put down for a show. For the future guidance of our friends in the profession who have gone home to think over and provide for us next year, I would say, Have plenty of people on your local committee and sub-committees, and never think of limiting your working power because it might be thought too large for the subject in view. Believe me, you will need it all.

After the new members were added to the Council, a Sub-Committee was appointed to draw up a set of rules and regulations for the future guidance of the Convention, and votes of thanks were passed to all who had worked so hard and so well. Then the Convention meeting at Glasgow began to melt away; the business was scarcely done when some of the friends had to hurry off to catch the train for Granton, where the steamer lay that was to convey them to London. Saturday afternoon saw most of the company scattered; that same evening our party took the Midland train for London, some of the Glasgow friends meeting us at the station to see us away.

It seems that a few of the members did not leave bonnie Scotland so quickly, for some of them were seen enjoying the shows at Glasgow Fair in the beginning of the week following the Convention. The Land o' Cakes suited them. I have nothing more to say. The comings and goings, the concourse and intercourse, teach but one lesson, for "As iron sharpeneth iron, so a man sharpeneth the countenance of his friend."

ECHOES FROM THE SOCIETIES.

THE shutter introduced to the members of the Photographic Society of France by M. de la Baume Pluvinel is ingenious in its conception, and if not theoretically perfect would most probably be found to work well in practice if used with care. The main difficulties in its application, as I see them, are not touched upon by Professor Stebbing in his description of it. As I read that description, the shutter consists of a disc of metal pivoted in the opening of a diaphragm, and the exposure is made by revolving the disc a half turn by means of a projecting needle or wire.

Obviously, if this arrangement is to be inserted by the ordinary diaphragm slot, the construction must be of the lightest, and I should like to ask how the necessary accuracy of fitting and working can be secured with so little material to work upon. In the first place, to render the shutter light-tight when closed the metal disc must be ground into the diaphragm aperture without any flange or bevelling to make the joint secure, otherwise the disc will not revolve. Then if it be so fitted it will be too tight to work easily and without causing a jerk to the camera during exposure. It will be difficult, too, to provide any efficient catch to prevent the disc rebounding after the exposure is made, as well as to secure from such flimsy material sufficient strength to withstand the sudden shocks of instantaneous exposures. The fact that a portion of the lens remains covered during the exposure would not, perhaps, present any practical objections, but how does the inventor hope to provide against the revolving disc wearing bright, and thus transmitting reflected light on to the plate? The idea is good, but requires some remodelling to render it truly effective.

The pocket camera devised by the same gentleman is of a more practical character, and I am surprised the idea has not been seized upon for the same purpose sooner. It consists of an extending body fixed upon the springs of an ordinary "Gibus" opera-hat, which upon pressure immediately flies out its full extension. The focus of the lens must, of course, be selected to suit the length of the springs, and for objects at varying distances it will be necessary to provide means for altering the position of the lens itself to a slight extent as the camera body is unchangeable. Some years ago Mr. W. J. Allsup described in the ALMANAC an extending camera front on the same principle for occasional use when a specially long focus is required. This was extremely simple and portable, occupying very little room when not in use and giving an increased range of about seven inches at a second's notice when required. But somehow or other the idea was never taken up.

M. Darlot's "detective" camera, exhibited at the same meeting, has, we are told, the form of an elaborately got-up gentleman's leather dressing-case. It seems to me that the manufacturers or "inventors" of detective cameras are vying with one another in attempting to rob the instrument of its "detective" or secret character and to reduce it to the level of the ordinary London "D," who is said to be invariably recognisable at a glance. What would the public, the police, and the detectives themselves, think of a man who was seen dodging about, say, a Socialist meeting in Trafalgar-square, with an "elaborately got-up gentleman's leather dressing-case" in his possession? I imagine the crowd would be on to the camera before the camera could be got on to the crowd.

W. Vogel, jun.'s, toning process for gelatino-bromide prints, which was subsequently discussed, is not to my idea one to be recommended. It is many years since cupric chloride was put forward as a toning agent capable of, at least, partly taking the place of gold, and so rendering the toning of albumen prints less costly. But it was at once pointed out, by Dr. J. Emerson Reynolds I think, that the tones so produced were not permanent, that, in fact, the copper compound is soluble in sodium hyposulphite, and that therefore any alteration of tone produced by the copper disappeared in fixing, and the nett result was just what would be produced by the gold alone. A print coloured to the proper tint or tone desired in the combined gold and copper bath would therefore be entirely changed in colour in fixing, being reduced in fact to the condition of a half toned proof.

In the case of gelatino-bromide, though the toning is performed after fixing, I do not see how the result can be any better, for though the tone may be at first perfectly satisfactory, its permanence is extremely doubtful. If we have to search no further than to hypo for a reagent that will act upon it, I do not think that it will prove capable of resisting the thousand and one agents that combine to destroy images that hypo will not touch.

A great deal has been heard lately about processes for the so-called photography in natural colours. The daily papers have gone into raptures through their "scientific" leader writers, and have admitted a lot of utter rubbish written principally by interested parties. The photographic journals have endeavoured to show what the "processes" really consist of, and so far as the photographic fraternity is concerned have no doubt succeeded in the attempt, but to reach the great body of the British public is beyond their powers. The first verdict of a photographic body, publicly delivered, was given at a meeting of the London and Provincial Photographic Association, where a long and anxiously expected portrait specially taken to illustrate the "process" and the vast strides made in "photography in natural colours" was exhibited. The verdict, it seems, was "not complimentary to the artist or the process." So far so good; but, as was suggested, cannot steps be taken to prevent the publication, to a non-scientific public, of statements which really amount to misrepresentations?

Some mis-understanding appears to exist in certain quarters on the subject of the different processes which have recently been before the public, all being classed alike as sailing under false colours. It is only fair to point out that the promoters of one process who recently modified the wording of their prospectus because it was stated that the language used was likely to mislead, go further than that, and are prepared to show the whole working of the process to any one who may be interested; also that they do not claim that their method is anything but an improved colouring process.

Papers on art-photography seldom contain or elicit anything that is particularly new, the subject having been so very thoroughly threshed out. Mr. Dunmore's paper on *Photography Past and Present*, read before the North London Photographic Society, contained, however, many excellent suggestions, and, what is more, elicited one or two noteworthy remarks in the course of the discussion that followed. For instance, when Mr. Pringle, in discussing the art *versus* the technical sides of photography, said that "no picture was ever the worse for the negative being technically perfect," he summed up the whole matter in a nutshell. It is too much the habit of those who write and talk on such subjects to "take sides;" the man of artistic proclivities preaches art and scorns the technics, while the *photographer*—using the term as meaning one who exposes plates and mixes developers—believes in nothing that is not a perfect negative.

Then, again, Mr. John Nesbit touched the right string when he expressed himself dissatisfied with his recent work as compared with that of former days, because "he felt that he had not kept pace with the opportunities now afforded for attaining perfection." There again is a sentiment that modern photographers should take to heart! What would Rejlander's pictures have been had he possessed the advantages of modern gelatine plates?

I do not quite follow the next speaker's remarks, in the course of which he alludes to photographers as being unable to "keep their minds free from matters pertaining to the dark room" while they are composing a picture. It is, perhaps, impossible to expect all to be perfect or all alike; the man who makes a picture, which, as Mr. Pringle says, is also a technically perfect negative, is the man who dissociates his mind from technical matters when engaged on the art side of photography. The operator who muddles up the studio and the dark room, or who, as Mr. Mackie describes him, is slave to a particular form of developer, is merely a *photographer* in the mechanical sense I have described above. I am afraid the latter are in the majority.

MONITOR.

ON A NEW PRINCIPLE FOR THE CONSTRUCTION OF PHYSICAL INSTRUMENTS OF QUANTITATIVE MEASUREMENT.

I.

THERE is a certain well-known piece of apparatus—a "philosophical toy"—to be found in most physical laboratories and elsewhere, which is known as the "Cartesian diver." It consists essentially of a hollow vessel partially filled with water and partially with air floating in a "glass," over the mouth of which an indiarubber or other elastic membrane has been stretched. This hollow vessel has a hole beneath, and is the better for having a weight attached to keep it right side up. It is so adjusted as to contain only just air enough to make it float. When pressure is applied to the elastic membrane a quantity of water is forced into the "diver," which accordingly becomes specifically heavier, and sinks to the bottom of the vessel in which it is contained. When the pressure is removed, the air within the "diver" expands to the volume it occupied before, forcing out again the water which made it sink, and the thing forthwith proceeds again to "swim." Such, at any rate, is the general theory of the affair, and though not quite so, it is substantially correct. Now, it must have occurred to Descartes (the inventor of it) that his "diver" presented the foundation of an instrument for the measurement of pressure, and this must have occurred to hundreds or thousands of others who have lived since Descartes died, two hundred and twenty-one years ago. Yet, so far as I have seen, it has not been applied for purposes of this kind until so applied by me. The difficulty of the thing is this: that a pressure sufficient to make the "diver" sink at all suffices also to make it sink to the *bottom* of the vessel in which it is contained, and a "levity" sufficient to make it rise at all also suffices to make it rise to the *surface* of the liquid in the glass. Temperature also affects the performance of the thing by contracting and expanding the volume of the air which it contains, with the results already given. Now, if the "diver" could be made to sink to depths which are definite and different under pressures which are definite and different too, it is clear that it could be made to measure any force translatable into pressure, as, for instance, temperature, electricity, mechanical motion, weight, elasticity, and the *radiant energy of the light of day*; and the thing in its various modifications could accordingly be used

as a barometer, a thermometer, a pressure gauge, a vacuum gauge, an ampère-meter, a voltmeter, a speed indicator, a balance for weighing, a measurer of elasticity, and (what interests the photographer most) a photometer as well, not to mention an anemometer, a chronometer, a tide gauge, a depth indicator, and a score of other things besides. It becomes, accordingly, a matter of philosophical importance that a solution of the problem should be found, and that we should have the means of making the "Cartesian diver" sink under definite pressures to depths which are definite too. This solution it has been my pleasure to seek, and my good fortune to obtain. Going more minutely into the theory of the "Cartesian diver" (which is here depicted), not only is a pressure which suffices to make it sink at all sufficient to make it sink to the bottom of the vessel in which it is contained, but in a certain sense it is more than sufficient for that purpose. For when the "diver" has sunk an inch, a tenth of an inch, or indeed any distance whatsoever, it is then subject not only to the pressure which made it sink but to the further pressure exerted by the liquid column beneath which it is submerged, and as this column increases with each increment of the descent, the "diver" reaches the bottom with an accelerating velocity under a pressure which is accelerating too, and when at the bottom the pressure of the liquid may in itself suffice to keep it there, even when the pressure on the elastic membrane has been removed.

In order to make the "diver" sink to a definite depth under a definite pressure, it is necessary that it should be relieved by the act of sinking of a portion of its weight greater than that of the water forced into it by the initial pressure which made it sink, and of the extra pressure of the liquid column which accumulates above it in the act of sinking. In short, it should get rid of a quantity of weight as it sinks, because it sinks, and which accumulates as the depth increases and in consequence of that increase in depth. I have adopted sundry devices for the accomplishment of this end; the first of these consisting of a chain of glass suspended from beneath the "diver" and reaching to the floor of the vessel in which it is contained, and on which it is deposited, link by link, as the "diver" is descending, and thus continually diminishing the load it bears at each increment of the descent and finding a different position of statical equilibrium for each pressure to which the apparatus is exposed. This result, however, obtains only under the influence of a constant temperature. In my next I shall proceed to show how the effects of temperature are nullified, or "compensated," and how the "Cartesian diver" is thus made into a true barometer, indicating the variations in the pressure of the outer air by the varying elevations at which it floats. This instrument, the "Cartesian barometer," is the foundation of all the other instruments I have already named.

D. WINSTANLEY.

CONTINENTAL PHOTOGRAPHY.

[Translations and Abridgments.]

PHOTOGRAPHY IN ANTWERP.

A MEETING of the new Section in Antwerp of the Belgian Photographic Association is reported in the June number of the *Bulletin* of that organization. M. Lunden presided, and among the matters of interest brought forward, M. Colon exhibited some prints upon albumenised paper of the ruins of Villers; these prints had been soaked, before the application of the mountant, in a bath of—

Alcohol	4 parts.
Glycerine	3 "
Water	1 part.

They were then mounted, and the superfluous moisture removed by blotting-paper, after which they were dried in the open air. These

operations were performed to prevent cockling during drying; in fact, the prints, although of the whole-plate size, were perfectly flat.

M. Maes, the chief Belgian collotypist, then proposed that an exhibition of the works of the members of the Section should be held in Antwerp next October. This suggestion was favourably received, and its further consideration was postponed until a future meeting. M. Maes then described his method of collotype printing, which is essentially that of Poitevin and Albert, after which he conducted the members of the Section over his works, and finally presented each of them with a print of the Place Verte at Antwerp, which included the Cathedral and the statue of Rubens.

ONE OF THE FATHERS OF PHOTOGRAPHY.

In the same number of the *Bulletin Belge* is an article on M. H. Bayard, who has just died at the advanced age of eighty-one. The author says that little is generally known of Bayard's early work, much about which is recorded in a scarce book written by Blanquart-Evrard, of Lille, and published in 1869. Blanquart-Evrard says that Bayard was chief of the *Bureau* of the Minister of Finances, and in that time which he had to spare from his administrative duties discovered a method of taking camera images upon paper. His discovery was complete, original, and without knowledge of the results to be later divulged by Daguerre and Fox Talbot. Bayard was a modest man; he knew that his invention was not perfect. Unhappily for him he but exhibited the picture and did not describe the method; this was captivating the eyes instead of seizing the spirit. If he had made his method public, the name of Bayard would now be as well known as those of Daguerre and Talbot. It was in 1838, six months before the publication of Fox Talbot's process, that Bayard exhibited to M. Desprez, member of the Institute, and two months later to Biot and to Arago, his photographs obtained in the camera. On the 24th of June, 1839, at a public exhibition in aid of the sufferers from the earthquake at Martinique, he placed on view thirty of his proofs. The Parisian observers thought them curious. A few days afterwards Daguerre divulged his discovery and his method of working; there was general excitement, and, despite the report of M. Raoul Rochette to the Academy of Fine Arts, which report was published in the *Moniteur* of November 13, 1839, Bayard and his invention were left in the shade, and almost entirely ignored.

The following was Bayard's process:—

1. Soak the paper for five minutes in a twenty per cent. solution of sal ammoniac, then dry it.
2. Float this paper upon a ten per cent. solution of nitrate of silver, and dry it in the dark.
3. Expose the nitrated side of the paper to light until it is nearly black, but take care not to reach the bronzing stage. Wash then in several changes of water, dry, and preserve in a portfolio for use.
4. Soak the paper for two minutes in a four per cent. solution of iodide of potassium, lay the white side of the paper upon a smooth slate, and apply the solution to the dark side with a large sable brush; then expose in the camera. The light will whiten it in proportion to its local intensity.
5. Wash the proof in several changes of water, then soak in a bath containing equal parts of water and ammonia, finally wash again in water, and allow to dry.

This article has appended to it in the *Bulletin Belge* the initials of M. A. de Blochouse, Vice-President of the Belgian Photographic Association.

PHOTOGRAPHY IN GERMANY.

At a meeting of the Berlin Society for the Advancement of Photography, the President, Dr. Vogel, announced that the Municipal Council of Vienna had contributed a subsidy of 35,000 florins for a Photographic Institute, of which Dr. Eder will be the director.—*Photographische Mittheilungen*.

PLATINOTYPY.

The son of Dr. Vogel has modified Léon Vidal's plan of turning the images on Eastman's paper into platinum, in the following manner. After development fix and wash, and place the images face downwards in the following bath:—

Potassium chloroplatinite	1 gramme.
Distilled water	1000 grammes.
Pure hydrochloric acid	10 centigrammes.

The prints should be left in the above for twenty minutes, then rapidly washed, and placed in a solution of chloride of copper; the silver of the image is then changed into chloride of silver, and the image takes a brown tone; if it looks too pale it can be darkened again with the oxalate developer; all this may be done in daylight. It can be afterwards further strengthened if necessary. Next fix to remove the excess of chloride of silver, then soak the print for five

minutes in a bath of alum and hydrochloric acid. Wash finally for fifteen minutes.—*Photographische Mittheilungen*.

INTENSIFICATION WITH PERMANGANATE OF POTASH.

M. Alf. Gendraud states that one day he placed a positive made by contact printing, and developed with ferrous oxalate, in a solution of permanganate of potash, in which it took a villainous brownish yellow colour. Merely as a whim he then poured a little iron developing solution over it; the positive immediately turned brown, the whites became clear, and the image had altogether become vigorously intensified. He repeated the experiment with another transparency, to which he gave longer immersions, and the intensification was most energetic, without degrading the whites.—*L'Amateur Photographe*.

IDENTITY OF THE PHOTOSALTS OF SILVER WITH THE MATERIAL OF THE LATENT PHOTOGRAPHIC IMAGE.

In the first part of this paper I described certain strongly coloured forms of silver chloride, bromide and iodide, obtained independently of any action of light, for which I proposed the name of photosalts, by reason of their identity with the products of the action of light on the normal silver haloids, both with the substance of the latent image itself and also with the principal results of the continued action of light on these haloids. It remains to prove this identity. First, as to identity with the product of the continued action of light.

If we expose silver chloride precipitated with excess of HCl to light, we get a deep purple-black substance which boiled with dilute nitric acid gives up a little silver, at the same time somewhat lightening in colour and forming a dull purple material which closely resembles some of the forms of photochloride described in the first part of this paper, most those produced by the action of sodic hypochlorite or of ferric chloride on metallic silver; it shows the same reactions with ammonia that they do. The brighter coloured photochlorides are not formed by the action of light on silver chloride. But these brighter coloured chlorides can also be shown to be formed through the action of light. Most salts of silver darken by exposure, and when these dark products are treated, first with HCl, and then, after thorough washing, are boiled with dilute nitric acid, we can obtain results perhaps as varied as those which I described in the former part of this paper as arising from purely chemical action.

Silver oxalate exposed for two days to sunshine, covered with water and with frequent agitation, changed to a deep brownish black, which by treatment with HCl became a little lighter. When this product was washed and boiled with strong nitric acid, it acquired a fine deep coppered colour, the acid taking up silver. This red substance dissolved in ammonia readily, leaving a small amount of black residue; the same with sodium hyposulphite.

(This examination, made a year ago, has recently been repeated with a view to obtaining a quantitative determination of the proportion of Ag, Cl contained in the red product. The exposure was for about a day; the oxalate at the end of the exposure seemed absolutely black. After treatment with HCl it assumed a purple-black shade. After thorough washing and boiling with dilute nitric acid, which removed a large quantity of silver, perhaps twelve or fifteen per cent. of the entire quantity, it had a fine lilac-purple colour. Analysis showed that it contained about one-half of one per cent. of subchloride, or more exactly, 0.45 per cent. Ag, Cl was found.)

The red chloride thus obtained from silver oxalate not only closely resembles the red chloride obtained by means exclusively chemical, but shows the same behaviour to reagents.

Treated with ammonia it dissolves, leaving a black residue. The formation of this residue takes place precisely in the same manner with both substances. As fast as the material dissolves the liquid becomes clouded and an extremely fine black substance seems to form within it, which gradually falls to the bottom.

Treated with solutions of the alkaline haloids, the red chloride derived from exposed silver oxalate remains unchanged after twenty-four hours' contact with potassic chloride, and becomes paler and more lilac under potassic bromide; under potassic iodide it becomes grey. These reactions correspond with those of the photochloride.

Silver phosphate belongs to the more sensitive silver salts and easily darkens in sunlight. In a few hours it becomes greenish all through, after which further exposure produces little visible effect. This product becomes with HCl quickly grey, and by treatment with nitric acid after washing, light pink.

Silver tartrate by exposure to sun became quite black. With HCl this changed to reddish grey or dull pink. This product well washed and let stand with cold nitric acid 1.36 became first lavender and then light pink.

Silver carbonate by prolonged exposure became greenish black, and with the above treatment yielded a dull pink photochloride.

Silver pyrophosphate, even by several days' exposure to winter sun, did not blacken, but assumed an ochreous or buff shade. With HCl this passed to a sort of salmon pink, and by heating a few minutes with dilute nitric acid, to a beautiful copper shade.

Silver acetate was singularly little affected by sunlight; it looked blackish, but on closer inspection was found to be very little altered. By the same treatment as above it yielded a pale pink photochloride. So far as examined, all silver salts thus treated yielded pink or red photochloride.

These facts may serve to show the identity of the photochloride with the principal product of the continued action of light on silver chloride and on other salts of silver, subsequently converted into chloride. I should wish, however, to use this word identity in a somewhat limited sense. When the photochlorides are formed by different methods without the aid of light hardly any two forms can be considered absolutely identical: they differ in colour and in proportion of subchloride, as already often mentioned, but they also differ in other respects, especially in resistance to reagents. Some forms are far more easily destroyed by nitric acid: those obtained by the action of sodium hypophosphite (as presently to be described) are amongst the most easily destroyed by nitric acid. There is variation, too, in the degree of their resistance to ammonia. Very similar differences are found in the stability of the photochlorides obtained by the action of light: some are much more readily attacked by nitric acid than others. The product obtained by the action of light on silver chloride resists ammonia more strongly than that obtained by the action of HCl on exposed silver oxalate. This last is quickly attacked. Generally, I think the dark-coloured forms are the most stable. At a future time it may perhaps be possible to distinguish more exactly between these varieties.

I next pass to the consideration of the identity existing between the photosalts and the material of the latent image. Before entering, however, on that matter, it is necessary to describe a reaction leading to the formation of these photosalts, somewhat differing from the reactions already mentioned, and which has important bearing on the subject.

The remarkable action which an alkaline hypophosphite exerts on salts of copper was described many years ago by M. Wurtz. Its action on silver salts, though there is no parallelism between the two, has enabled me to find a key to some of the great difficulties of the latent image. A dilute solution of sodium hypophosphite if poured over a mass of chloride, bromide, or iodide of silver, formed in the absence of light, produces no visible effect, but has the property of bringing those substances into the condition in which they exist in the latent image. Applied in strong solution and with the aid of heat, it produces brown-purple photochloride, bromide, and iodide of silver. I will here briefly describe the first of these compounds in order to continue the series of photochlorides, and then pass to the consideration of the latent image.

Photochloride of Silver by Sodium Hypophosphite.—Silver chloride freshly precipitated with excess of HCl and well washed, placed in a flask with a strong solution of sodium hypophosphite and heat applied, begins to darken before the boiling point is reached. Actual boiling for ten or fifteen minutes gives a deep chocolate colour. This product well washed, and freed from traces of metallic silver by cautious boiling with very dilute nitric acid, has a pink, red, or brown colour, varying in intensity according to the length of the action. Sometimes a lavender shade is produced, and this is more apt to be the case when the silver chloride has been precipitated with excess of silver nitrate instead of excess of HCl. Silver determinations of two specimens of the purified product were made, indicating the presence in one specimen of 1.77 per cent. of subchloride; in the other of 3.53. By the continued action of heat for many hours a complete reduction to metallic silver takes place. Photochloride obtained in this way has generally a brown or dull purple colour. Boiled with nitric acid, it is apt to break up in as many minutes as some other forms would require hours for decomposition, yielding white chloride, whilst the nitric acid takes up small quantities of silver.

IDENTITY OF PHOTOSALTS WITH THE MATERIAL OF THE LATENT IMAGE.

It is proposed here to show: 1st. That in the entire absence of light, sodium hypophosphite is able to affect a sensitive film of silver haloid exactly in the same way as does light, producing a result equivalent to a latent image formed by light, and capable of development in the same way as an actual impression of light. 2nd. That these two effects, the impression produced by hypophosphite and that by light, comport themselves to reagents exactly the same way, and seem every way identical. 3rd. That the image produced by hypophosphite on silver chloride always gives rise to a positive development, but on silver bromide may give rise either to a direct or to a reverse image, both of these effects corresponding exactly with those of light. More than this, sodium hypophosphite may be made to reverse the image produced by light on silver bromide, and conversely light may be made to reverse the action of hypophosphite. So exact a correspondence in these remarkable properties can scarcely be fortuitous.

I.

A silver haloid formed in the absence of light and subjected to the action of sodium hypophosphite gives rise to the gradual formation of subsalt, which combines with the normal salt in the manner described in the previous part of this paper. This action of the hypophosphite closely corresponds with that of light. In its initial stages it is invisible, but can be brought out, in both cases by development. If we form a film of chloride, bromide, or iodide of silver, and with a glass rod dipped in solution of hypophosphite make marks upon it, these marks can with

the utmost ease be developed in precisely the same way as an image produced by exposure to light.

A very simple mode of operating consists in imbibing photographic paper with a solution of an alkaline haloid, drying, applying a silver solution, and then thoroughly washing, all of course with careful exclusion of active light. If the silver solution is acidulated with nitric acid, a drop to the ounce, the result is brighter, but this is not important. In any case the washing must be thorough.

Marks made on this paper can be developed with the oxalate developer with the utmost facility. If a strong solution of hypophosphite is applied cold, it may be washed off at the end of a minute, but a stronger impression is obtained by allowing it to wait a half an hour before developing. Or the action may be accelerated and increased in strength by laying the freshly marked paper on a hot surface, or better, by steaming it, before applying the developer. A convenient mode of steaming is to lay two pieces of glass on a small water bath kept boiling, with a space between them. Over this space the paper is rested for two or three minutes. Paper prepared with a solution of KCl, KBr, or KI, dried, and floated on acidulated solution of silver nitrate and well washed, if marked with strong solution of hypophosphite and steamed for two or three minutes, will develop the marks as black as ink on a white ground. The use of heat simply gives a blacker development, but a very vigorous image may be got without. (A similar result may be obtained by substituting for the hypophosphite a dilute solution of potash and an oxidable organic substance. With milk sugar the action is very energetic and heat is quite superfluous.)

Both these are the initial steps of reactions which when prolonged result in the visible formation of the coloured photosalts. It is a matter of interest that sodium hypophosphite, which produces the above-described effects, has no developing power whatever.

II.

The two impressions, that formed by light and that by hypophosphite, are similarly affected by reagents. As an example of this identity of effect produced on the two impressions, I first take the action of nitric acid.

Chloride, bromide, and iodide papers were exposed to moderate diffuse light under a screen with openings, for a proper time to form a latent image, the chloride and bromide for four or five seconds, the iodide for twenty or twenty-five. They were then cut into halves and one-half of each was soaked in strong nitric acid for five minutes. These halves were then washed for some hours, and were developed along with the halves not so treated. Result was, latent image on silver chloride almost if not quite uninjured; on silver bromide, somewhat affected but still strong; on silver iodide, entirely destroyed. Similar portions of the same papers were then marked with hypophosphite, and were cut into halves and one-half was subjected to the action of nitric acid in exactly the same way as the previous. The result was exactly as before. The hypophosphite marks on the half of the chloride paper that had been treated with acid came out in development as vigorously as on the half that had not been treated. The bromide paper showed the marks weakened by the acid but still strong; on the iodide not a trace appeared. In all respects the result was the same—what the one resisted the other resisted, what destroyed one destroyed the other.

Another confirmation is presented by the action of the alkaline haloids upon the latent image. The latent images produced by light on chloride, bromide, and iodide of silver, were all treated with cold and moderately strong solutions of potassic chloride, bromide, and iodide for half an hour, and were then subjected to development. It was found that all three silver salts bore the action of potassic chloride and bromide fairly well, the images were somewhat weakened but strong developments were obtained without difficulty. But when potassic iodide was applied the latent image was totally destroyed. The visible effect of the alkaline haloids on the photosalts exactly corresponds with their action on the latent image. Potassic chloride and bromide applied in moderately strong solution and cold have little effect, but potassic iodide quickly destroys them.

Therefore the action as well of nitric acid as of KCl, KBr, and KI, is exactly the same on the latent image impressed by light on AgCl, AgBr, and AgI, as it is on the corresponding photosalts.

III.

The impressions produced by alkaline hypophosphite upon silver chloride always give rise to correct images, darker than the ground on which they are formed. The same substance produces an impression on silver bromide which may by development produce either a direct or a reverse image. So that there is a perfect parallelism with the action of light.

The reverse action of light, sometimes called solarisation, shows itself as follows:—A film of bromide being exposed to light, part covered by an opaque screen, the exposed portion receives an impression capable of development, and this impression grows in strength to a certain point, then recedes and reaches a condition in which it is less susceptible of development than before exposure. All bromide films, even unexposed to light, will darken in a developing solution in time. The portion that under the action of light has reached the reversed stage resists the reducing action of the developer better than that which was not exposed at all, and, consequently, appears after development as light on a dark ground, and is, therefore, a reverse image. As to the cause of this action we are

as yet wholly in the dark. If the continued effect of light was simply to restore the affected part to its original state we might attempt an explanation by affirming that the continued action of light undid its own work. But the fact of the resistance to reduction being greater than before exposure shows that some as yet unknown action of light is in play. The reverse action cannot be due to oxidation, as has been suggested, because hypophosphite reverses and certainly cannot oxidise.

The reversing action of light on silver bromide finds its counterpart in the action of sodium hypophosphite. If we take bromide paper (it is immaterial whether in making it the bromide or the silver solution be applied first, but for these experiments on the reversal of the image it is essential that a pure neutral silver solution be employed, and that after the second solution has been applied the paper should be thoroughly washed, all the operations being of course performed by inactive light)—if we take such paper and make marks on it with a strong solution of hypophosphite, and then throw the paper into potassio-ferrous oxalate, we shall get a direct development; the marks will be stronger than the ground. If now we continually weaken the hypophosphite solution, we shall presently reach a point at which these marks are in development almost wholly indistinguishable from the ground on which they were made. But, continuing the dilution still further, we presently reach a point at which the marks reappear, but this time reversely; as lighter marks on a darker ground. This result is obtained with about a two per cent. solution; the first-mentioned effect comes with a solution of twenty-five or thirty per cent. So that according as we use the hypophosphite solution stronger or weaker we obtain exactly opposite effects. Here the parallelism is striking but not perfect—at least it remains to be explained why the action in the two cases proceeds in a reverse order. All the other reactions show a perfect identity. Time will also sometimes produce the same effect as dilution. Paper marked and put away for twenty-four or forty-eight hours, giving at first a direct image, may after that time give a reverse one. This effect is extremely uncertain and, I think, exceptional. I have kept very many pieces for periods, from a few hours to several weeks, which first and last gave direct images only; a few became reversed. But the experiment itself, the opposite effect of strong and weak solutions, is liable to no such uncertainty.

Again, we may make light and hypophosphite interact, and each reverse the other's action. To make hypophosphite reverse the action of light, I take a piece of silver bromide paper, expose it to the action of diffuse daylight for a few seconds, then taking it to the dark room make marks upon it with a glass rod dipped in solution of hypophosphite. On developing with potassio-ferrous oxalate the marks appear lighter than the ground. Or, what is perhaps more striking, we take two pieces of such paper, retain one in the dark room and expose the other from five to twenty seconds to diffuse light, then make marks on both with a glass rod dipped in strong solution of hypophosphite, and then, after allowing a few minutes for the hypophosphite to act, place them both in a solution of potassio-ferrous oxalate. The marks will develop, in the one case, as dark on a light ground, in the other (that exposed to daylight) as light on a dark ground. We have here made the hypophosphite imitate the action of light: it has reversed the image in the same way as would result from a prolonged exposure to light. It will next be shown that light may be made to imitate the action of hypophosphite and reverse the effect already produced by that or other reducing agent.

If we take the red or purple silver bromide, preparing it with exclusion of light, and the same precaution as in the case of a dry plate, and extend it over paper (it is best, though not essential, to mix it with a little gelatine to enable it to retain its hold on the paper in the subsequent treatment), dry it and expose it to light under a screen such a piece of opaque stiff pasteboard with openings cut in it: then apply potassio-ferrous oxalate, we shall obtain a very remarkable effect: all the parts exposed to light take a reversed development and appear as lighter spaces on a dark ground. And this goes so far that we may expose till we get a visible and quite strong image, darker than the ground, and yet in development this darker portion will come out lighter than the ground. Indeed, I have one specimen which shows almost white figures on an intensely black ground. Before development these light figures were brown, by exposure to light, on a rose-purple ground. I have seen few more curious results than this.

From the foregoing it follows that red bromide, notwithstanding its intense colouration, is in the same condition respecting light as normal silver bromide that has received an impression of light so strong that any further influence of light would cause reverse action, only that a vastly larger proportion of its molecules are affected. In the case of the latent image formed by light on normal bromide, it would seem that the particles affected, although numerous enough to serve as a basis of development, are still too few and too scattered to be visible or affect the colour. The photobromide, on the contrary, has its mass made up of them. Then if exposed to light the light carries them a stage farther—brings them to the reverse or "solarised" condition, and the parts affected by light develop less strongly than those not exposed. So light can act the part of hypophosphite and hypophosphite that of light, interchangeably: each can produce a direct action, each a reverse, and each can reverse the other.

It then appears that in all the numerous ways in which it is possible to compare the photosalts with the material of the latent image they are

found to be identical. The proofs based on development generally, and especially on the reversal of the latent image, seem very strong, and these receive additional support from the exact identity of reactions shown by the photosalts and by the material of the latent image. The question of the identity of the photosalts with the products of light on the silver haloids might perhaps be left with some confidence to the cumulative proofs here offered. But I hope to be prepared to give in the next number of this Journal additional evidence from a new direction.

M. CAREY LEA.

PRINTING IN CARBON, AND OIL COLOURS, AND PHOTO-LITHOGRAPHY.

[A Communication to the Dorset Amateur Photographic Association.]

THE subjects of printing in carbon and photo-lithography should be of peculiar interest to members of a Dorset Photographic Association, for though it is by no means a generally acknowledged fact, it is an undeniable one, that to Dorset belongs the honour of the inventions.

I propose to-day, at your invitation, to give you some account of these discoveries and of the steps which led to them. I shall illustrate the remarks I have to make with specimens of earlier and later work done by them, and I propose further to add some particulars of a later and most important discovery made by their inventor, of a method by which prints can be produced in oil colours. The process is at present a secret, but I shall be able to show you results produced by it which will prove to you its great value. Had the process been taken up some years ago, in all probability it would have revolutionised the art of photographic printing, for the process is exceedingly simple—prints of every gradation of tone and colour can be readily produced by it. Moreover, the prints are permanent to a degree that no other photographs are, for they are capable of resisting tests so severe that no prints by any other known process could stand them. The process is far in advance of that which the editor of one of the principal photographic papers of the day stated would, if discovered, "be one of the greatest discoveries photography has ever known."

I made the acquaintance of the inventor, Mr. Pouncy, of South-street, Dorchester, some time before he applied himself to the solution of this problem—the "philosophers' stone" to photographers of that day. I was a constant visitor to his studio and laboratory. I followed with interest the development of his invention, and experimented myself in the same direction, and thus gained a practical acquaintance with the subject. About the time Mr. Pouncy commenced his experiments, photographers were beginning to find out that silver prints contained in themselves the elements of decay, and must ultimately fade, and were looking out for some process by which photographs might be produced in permanent colours. Amongst other chemical substances from which more reliable results were hoped, carbon naturally suggested itself as one of the most suitable; for carbon is the most durable of all chemical matter, it combines with oxygen alone, and with that only at a very high temperature. But whilst chemists were looking forward, and scarcely hopefully, to a time when photographs might be produced in carbon, and photographers were beginning to interest themselves in the search for this, the photographic philosophers' stone, Mr. Pouncy was already far advanced with his process.

In 1838, Mr. Mungo Ponton made the discovery that bichromate of potash was capable of producing under the action of light a photographic image, and by its means he produced the first fixed photograph. The colour of the print was not satisfactory, and Mr. Ponton tried to improve it by staining the solution, and with the addition of sulphate of indigo he succeeded in obtaining a picture in various shades of green. Mr. Ponton's experiments may have suggested to Mr. Pouncy the possibility of obtaining a permanent print by the use of the bichromate of potash, though he adopted altogether a different line in his use of it. The first idea which occurred to him was, that since bichromate of potash, under the action of light, would produce a photographic image, it might in combination with carbon fix that also. He mixed carbon with his bichromate, applied it to paper, and for the first time a black surface instead of a white one was used to print upon. After many experiments he found that the black surface did not prevent the light from operating, and that a picture could be obtained. This was an important point, but the experiments did not result in a satisfactory print, for the carbon washed up in developing; some cement was required to unite the carbon and the bichromate. Amongst other substances treated for this purpose were gelatine and gum arabic, and, at length, by means of the latter, satisfactory prints were obtained.

I would here remark that Mr. Pouncy preferred gum arabic to gelatine as a cement for the carbon, mainly because he was from the first in search of a photo-lithographic process, and gum arabic, which is largely used in lithography, afforded for that reason the surest promise of success. In photo-lithography there was also the fact which might have had some weight with him, that the gelatine print required the assistance of a brush in development, or at least the use of hot water, whereas the gum arabic print could be developed by the use of cold water alone simply poured over the print. But I should like to make it clear that Mr. Pouncy did produce carbon prints from the first by the aid of gelatine as well as by the use of gum arabic.

Early in March, 1858, Mr. Pouncy sent two prints by his new process to the Editor of the *Photographic Notes*, one a copy of an engraving of Captain Cook, the other from nature, a photograph of Bingham's Melcombe. These, the first carbon prints ever exhibited, were received by the Editor on March 5. The Editor considered the matter of such importance that he forwarded the prints to H.R.H. the late Prince Consort through his private secretary, Dr. Becker. Dr. Becker, in a note from Osborne dated March 15, 1858, stated that he had shown the prints to His Royal Highness, "who thought them very remarkable and representing a most important step in photography." He further added, "The Prince will be glad to hear of whatever steps he (Mr. Pouncy) may take to make his discovery most generally useful."

I have the pleasure of showing you one of these original prints; you can therefore form your own opinion of them and mark for yourselves the high degree of excellence attained by Mr. Pouncy from the first, and you will not wonder that some persons refused to believe that they were carbon at all, but believed that they were silver prints on plain paper, and others that they were simply engravings. H.R.H. the Prince Consort subsequently subscribed £10 of the £100 asked by Mr. Pouncy for giving his process to the public.

The carbon prints first produced were deficient in half tone. You will understand why this was the case; the negative was placed over the black sensitised surface of the paper, a long exposure was required so that the light might penetrate to the paper support, or the colour would wash off in developing. For reproduction of a line engraving or any subject in black and white, this was of no consequence, but the prolonged exposure and the action of the light through the whole thickness of the sensitised composition over the shadows and half tints allowed of little gradation of tone.

Mr. Pouncy saw that in order to produce a print from nature with every gradation of tone, it was necessary that the light should act on the composition next the paper first. He therefore tried the effect of placing the negative at the back of the prepared paper. This had the desired effect; the print presented a granular appearance from the printing in of the grain of the paper, but the half tones were represented in every shade as in the negative, and the appearance of grain was subsequently reduced by the use of a thin paper previously prepared, or by rendering the paper transparent by means of Young's paraffine. This method of printing, however, introduced a new difficulty—the prints were reversed, the left side appearing on the right, the right side on the left. With a portrait this was not of so much consequence, but views of places became almost unrecognisable. The new difficulty was promptly met by an ingenious device. If you take a piece of sensitised albumenised paper and place it under a negative with the unprepared face to the negative, and print in the ordinary way, you will find a faint image on the sensitised face of the finished print, a rough image on the other, but on holding the print up to the light, you will find a perfect image in the substance of the paper, and a negative so made can be printed from either side. I show you a negative on albumenised paper made in this manner. Another and still more effective way of getting over the difficulty was to coat the negative with a solution of indiarubber in benzole, or some such solvent. When dry, a second coat was given. This was allowed to harden, when the corner of the picture was raised and the whole stripped from the glass. I hand you a film negative which I stripped in this way more than twenty-five years ago. It has been lying about since, and no particular care has been taken of it. It will give as good a print as ever. It might suggest a method of stripping gelatine films, though it must be remembered that there was much more in common between the collodion film and the solution of indiarubber in spirit than there is between the aqueous gelatine film and the solution in spirit.

I have previously noticed that the late Prince Consort gave £10 towards the sum asked by Mr. Pouncy for giving his process to the world. This was made public through the *Photographic Notes* towards the close of the year 1858.

The process is simple enough. It may be shortly described as follows:—Take equal parts of a saturated solution of bichromate of potash and of gum arabic made to the consistency of varnish. Add the fourth of a part of vegetable carbon ground very fine. Coat paper with the solution by means of a broad camel-hair brush, and expose the paper under the negative when dry for from five to fifteen minutes. To develop, soak in water, afterwards wash under a tap.

As to the permanence of the prints, at a meeting of the French Photographic Society in August, 1858, M. Giraud stated that he had tested one of Mr. Pouncy's prints and found it to resist the prolonged action of concentrated nitric and hydrochloric acid, aqua regia, cyanide of potassium, and that none of these energetic agents affected it in the least.

I will show you some specimens produced by this early process whilst we go on to speak of photo-lithography. Notice in particular the carbon print of Melrose Abbey; it received the silver medal of the Edinburgh Society in 1863. The Committee sent down the negative to Mr. Pouncy, and were thus able to form an accurate opinion as to the capabilities of the process, as they could compare the carbon print with the silver prints made by themselves from their own negative.

Before commencing the account of the invention of photo-lithography, it might be advisable to give an outline of the art of lithography as it is commonly practised. The lithographic stone is rubbed down to a level

and smooth surface. The subject is drawn with greasy lithographic ink on prepared paper, the drawing is transferred by pressure to the stone, and is slightly etched in by a weak solution of acid. The stone is then washed and coated with a solution of gum arabic. Being of a porous nature, the gum is absorbed by the stone, except in those parts which are covered by the drawing in greasy ink.

A roller charged with printing ink is now rolled over the stone, the lines of the drawing receive the ink, the other parts of the stone, moist with the damp gum, reject it. Printing paper is now laid upon the stone and the whole subjected to pressure, after which the print is removed and the process of printing repeated.

I have noticed that Mr. Pouncy was in search of a photo-lithographic process from the first. In 1858 and 1859 he was working incessantly and laboriously, early and late, first at carbon printing, then at photo-lithography. With every advance in carbon printing he sought to make a corresponding advance in photo-lithography, and much of the experience gained in working the former process was useful to him in his experiments with the latter—the methods by which he obtained reversed prints and reversed negatives, for instance, were invaluable in the stone printing.

His first endeavour was to produce an image on the stone which should retain the printing ink from the printing roller passed over it, whilst the bare parts of the stone would reject it. Every experiment in this direction resulted in imperfect prints; there was a difficulty in fixing the picture on the stone so as to bear the wear and tear of printing.

About this time M. Poitevin—of whom we shall have to speak again—and possibly others were at work on photo-lithography. M. Poitevin was trying a secret process, but enough transpired to show those who were familiar with what had been already accomplished that success was not attainable in the direction in which he was working. He was, in all probability, using albumen, or some such substance, sensitised with bichromate of potash; he printed direct on to the stone, and from one fact which transpired that after five or six impressions the image rolled off in the printing, we gather that he was attempting to print as Mr. Pouncy did at first, from a *positive* image photographically fixed on the stone. The difficulty of fixing by means of photography an image which would print on the stone did not trouble Mr. Pouncy long, he overcame it by the most ingenious and simple means. The attempt to print from the *positive* image was a failure, because no substance could be used to form the picture which would unite with the stone so intimately as to bear the wear of printing. But why should he not throw a *negative* on to the stone, so as to leave the lines of the picture bare whilst covering all other parts of the stone? All that would then be necessary would be to pass the roller charged with printing ink over it, when all the lines of the picture represented in bare stone would receive the ink, whilst the ink would not penetrate to the parts covered by the negative, which might then be washed off, ink and all, leaving the picture in printing ink on the stone; the stone might then be etched in, gummed, and printed in the usual way. This was tried and was completely successful.

The lithograph I hold in my hands is one which was issued and presented with the *Photographic Notes* of December 1, 1859. It appears to be a copy of one of Albert Dürer's prints. It is not the best specimen of Mr. Pouncy's work at this time, but the Editor wished to print a specimen with that number of his paper, and as the time was limited, Mr. Pouncy printed a stone which had this picture upon it, and which first came to hand.

W. MILES BARNES.

(To be continued.)

SOME PHOTOGRAPHIC HERESIES.*

LET us take a comprehensive view of this subject, and see how it looks from a distance in a good light. The universe, and all contained therein, visible and invisible, has to be photographed. Who is to do it? We professionals cannot begin to do it; it is much too large a contract. Then what are we to do? Are we to be like dogs in the manger, or cheerfully recognise the valuable service our amateur brethren are rendering in this work? How much do you think of the work done by amateurs would come to the profession? Less than one-tenth; that is to say, more than nine-tenths of the work done by amateurs would never be done if they did not do it. Then let us not forget the splendid services amateurs have rendered the art-science in the past. Surely they have earned their diploma. Then away with petty jealousies and such old cries as "The craft is in danger!" If the craft is in danger, it is from within, and not from without; and it will generally be found that the most jealous are the incompetent—those who have no special skill to rely on.

There is a general superstition in the profession that a north light is a necessity for a portrait studio. In fact, I very much doubt if there is a south skylight in this city. See the trouble they have gone to all down Arch and Chestnut streets to obtain a north light; they have had to either build over two houses or spoil the length of the studio. Now, I have worked under many skylights, and prefer a south light every time.

* Concluded from page 459.

Speaking of portraiture, a portrait combination lens is supposed to give great roundness of image; of course opticians favour this view, as well as many photographers. My opinion is, it is a question of lighting, and has little or nothing to do with the lens.

Mr. Burton has lately been finding fault with the term "depth of focus," but he does not suggest a better. He says it is impossible that more than one plane can be perfectly defined at once by any lens, no matter how small the diaphragm used. Truly, we are getting things down very fine. Why did he not go further, and object to the term "flatness of field," because no lens has a perfectly flat field? Why did he use the term "perfect definition," when he knew that the correction of all photographic lenses is a compromise, and that the photographic lens has not yet been made perfectly free from astigmatism? Consequently, there is no such thing as perfect definition. I notice some writers on photographic optics have lately been using the term "penetration;" but is it any improvement on "depth of focus?" I think not; besides, it is not nearly so expressive. The English language is a very good one, but, like many other things, is not quite perfect.

Another heresy of mine is that every live photographic society should have a standing committee, which may be called the "Research Committee," composed of three experts, who should, if possible, be, either individually or collectively, skilled in photographic chemistry, photographic optics, and mechanics, with power to add to their number for special work. They should report at each monthly meeting on such matters as might have been referred to them, or in their judgment they may deem worthy of investigation. One part of the order of business should be "Report of Research Committee." A question may be asked which no one is able to answer, such as, "Is chloride of sodium a restrainer or an accelerator?"—referred to the Research Committee. An optician brings out a new lens or a new invention, or a plate maker a new plate, for which they claim certain possible or impossible qualities. Knowing a society has a competent Research Committee, samples are forwarded for examination, and the reports of such committee would be of great value to the members and the photographic world.

I have heard it stated, on good authority, that a diaphragm which expands and contracts during exposure would not give good definition with a single lens, but having tried it I can say it is a mistake, for it does not injure the definition in the least, but improves it.

J. Traill Taylor, in a lecture on lenses recently, proposed as a corrector for single lenses a pair of common, cheap lenses, to be placed near the diaphragm; one a periscope of short focus and the other a concave lens of the same focus. I have tried it, and having no focus it has no effect, as we might expect.* This gentleman is usually so very accurate, especially in optical matters, that I am the more surprised he should make such a suggestion without having first tested it.

I was speaking of this to a gentleman whom you all know, and he said, "Have you seen my plan of doing that?" I answered, "No; what is it?" He said, "You are aware that a square diaphragm gives cushion-shaped distortion." I replied, "I did not; but I did know that placing the diaphragm behind the lens gave that form of distortion." "Well," he said, "a square diaphragm gives it, too; now I make a round diaphragm, and outline a square outside of it, and in each corner of the square I cut out a triangular aperture, which will give a rectilinear picture." I tried the square diaphragm, and found it did not give the cushion distortion as stated, so did not think the other was worth trying, as the distortion is not influenced by the shape of the diaphragm but by its position. I think the single lens has a great future before it, however some may despise it.

One article of my photographic creed is, I believe in the capabilities of a plate of the most exalted sensitiveness, the largest diaphragm, and the shortest exposure that will give the amount of detail and definition desired.

CHARLES TAUSCOTT.

Our Editorial Table.

THE A B C GUIDE TO AUTOTYPE PERMANENT PHOTOGRAPHY.

London: The Autotype Company, 74, New Oxford-street.

STANDING on the shelves of our reference library is a series of six editions of prettily illustrated and lucidly written autotype manuals, each edited and revised in succession upon previous issues by Mr. J. R. Sawyer, the director of the works. To these we have had frequent occasion to refer when we were desirous of sharpening our mind in either the principles or practice of the ever fascinating carbon process.

The *A B C Guide to Autotype Permanent Photography*, by the same author, may be roughly stated to be a "boiling down"—a species of practical quintessence—of all that has previously emanated from this enterprising firm in the elucidation of pigment printing, and we

* The writer of the above has failed from lack of knowledge as to how such a combination should be used. The two supplementary lenses counterbalancing each other, or nearly so, little if any alteration will be made in the focus; but if correctly put together there will be so much marginal displacement as to secure, with absolute certainty, freedom from distortion. He must try again, and if he does so intelligently he will quickly unsay what he has here said.—Eds.

are sorry indeed for the intellect of the man who, with such a "Guide" in his hands, could fail to produce excellent work.

Having devoted a few pages to the history of carbon, or pigment, printing, Mr. Sawyer, in what country newspapers would call a "few and well-chosen words," describes the various pigmented tissues manufactured, their colours and uses; passes on to the general principles of single and double transfer; and then, before the reader is well aware, he is in the midst of the manipulatory details of undoing the carbon roll as it comes from the factory, sensitising it, which is simplicity itself, drying, exposing to light, and afterwards developing the image.

After treating the details of single and double transfer on paper, our author then goes practically into the application of the process to opal printing and various other applications of the art, touching upon the printing-in of skies and backgrounds, transparencies and lantern slides, concluding by a treatise on failures and their remedies.

We cannot too strongly recommend this well-digested manual to all who desire to become acquainted with pigment printing. It contains two illustrations, one of them, a portrait, being from a negative by Byrne, of Richmond; the other, a photograph taken in the interior of the Autotype Works, showing the method of development.

PATENTS COMPLETED.

A NEW OR IMPROVED MACHINE FOR CUTTING PHOTOGRAPHIC AND OTHER GLASS PLATES.

No. 11,231.—BENJAMIN JOSEPH EDWARDS, The Grove, Hackney, London.—*September 3, 1886.*

I PROVIDE a table or platform of suitable size, upon which the sheets of glass to be cut are placed one at a time, and I make the surface of the table of two slightly different levels on either side of the line of cut, to facilitate the snapping of the glass, as described hereafter. At one side of the table I hinge a flap (one side of which forms a guide for cutting), and along the opposite side of the table I form a raised stop, upon which the flap rests when in use, just clear of the sheets of glass to be operated upon. At the end of the flap I form a second smaller flap, which may be hinged or made of some suitable flexible material, and on the under sides of these flaps I form suitable projections, which can be pressed upon the glass on either side of the line of cut, and thus by the aid of the inequality of the surface of the table snap the glass, in order to effect complete separation.

When the sheets of glass are to be bisected I fit a right and left-handed screw in the fixed bearings below the table, and upon it I arrange nuts equidistant from the centre, which travel horizontally to and fro along the screw (when turned by a suitable wheel or handle), thus pushing the sheet of glass into position and gripping it ready for cutting in the exact centre.

When the sheets of glass are to be cut to certain dimensions (not bisected) I make use of a similar platform or table, and on one side I fit a suitable sliding guide, which may be adjusted for various sizes by means of a scale or by a spring bolt fitting into notches or other convenient device. The sliding guide or fence is set at right angles to the stop or rest, against which the sheet of glass is placed, and the flaps being also at right angles to the stop, the sheet is cut square immediately on being placed in the machine without special adjustment.

By means of any ordinary hand diamond tool drawn along the edge of the flat above described the sheet of glass may be bisected or cut square to any required dimensions with great accuracy and rapidity.

As hand cutting is liable to failure from inexperience, carelessness, or other causes, I provide a frame or baseplate, which may be used in combination with the above-described tables, which are made interchangeable. To this frame or baseplate I fit grooves or guides along which the tables, which are furnished with corresponding guides or projections, are made to travel. At the far side of this frame I fix a standard or bracket, and in its upper end I form adjustable bearings to receive a rocking arm or lever (in one end of which I fix the diamond tool), and which may be regulated to give any desired pressure upon the diamond by means of sliding or adjustable weights, or by a spring, or by both combined. As a guide for the diamond tool I provide a wheel which I pivot in the end of the rocking arm, and then adjust the diamond so that the point shall project slightly beyond the rim of the wheel. When the wheel arrives at the edge of the glass the diamond is lifted by it into position for commencing the cut, and at the end of the cut it runs up a slight incline, formed on the flap, and is then drawn over by means of a small spiral spring or other suitable device on to the surface of the flap, upon which it runs during the return stroke, keeping the diamond entirely off the glass; at the hinge end of the flap a suitable guide conducts it again into position for cutting.

IMPROVEMENTS IN APPARATUS FOR PRESERVING AND CHANGING SENSITIVE PLATES USED IN PRODUCING PHOTOGRAPHIC PICTURES.

[Communicated from abroad by Messrs. Koppe & Moh, of Goerlitz, in the Empire of Germany, Manufacturers.]

No. 6032. EDMUND EDWARDS, 35, Southampton-buildings, Chancery-lane.—*April 25, 1887.*

This invention relates to the apparatus used for obtaining photographic pictures upon what are known as dry sensitised glass or other plates, and more

especially to apparatus by means of which such plates can be changed when required, a fresh sensitive plate being substituted for one which has been exposed in a camera and a picture obtained upon it.

It has for its object a novel method of constructing and using such apparatus, so that it is light, cheap, and easily used, whilst it occupies little space, separate dark slides for each plate being dispensed with.

For this purpose a bag is used, of flexible material impervious to light, and so made and arranged that the sensitive plate or plates contained in it can be transferred to or removed from the camera when required, the back of the latter being specially constructed to receive the open end of the bag.

The flexible bag, of a size adapted to the sensitive plates which it is to contain, is made of silk or other suitable fabric, coated inside with a lining of indiarubber, gutta-percha, or other smooth substance of the like kind, of sufficient density to completely exclude all light.

The smooth inner surface coming in contact with the surface of the sensitive dry plate does not at all injure the latter. The bag is made of sufficient depth to allow its open upper end (when the plate or plates are in it) to be folded over against its side. This open upper end or mouth is surrounded by a metal frame, to which the edge of the fabric is attached.

The sensitive plates being dropped into the bag in a dark place, the upper end is folded down as described, and is held down by an elastic band passed round near the upper end of the plates, the extreme open end and metal frame hanging loose below the band. In this way all light is entirely excluded, and the plates may be preserved for any length of time without losing their quality.

When the plates are to be used, the bag is connected to the back of the camera, or to the dark slide which fits upon the back of the camera in which the pictures are to be taken. The lower edge of this slide is open, and is provided with a groove or guide, into which the metal frame at the mouth of the bag is inserted, and is then held firmly in its position by means of a sliding or other clamp or catch, the fabric of the bag which fits round the metal frame serving to make a perfectly tight and elastic fitting between the parts. When the bag has been thus arranged, the elastic band already described may be removed, and the sensitive plate or plates raised up into the dark slide above.

Where two sensitive plates are used, they may be supported by a sheet metal plate between them, the ends of this plate being bent over in opposite directions, one to the right and one to the left, so as to hold both sensitive plates firmly in position.

The dark slide may be provided with a novel device for adjusting the position of the dry plate. This consists of a revolving disc recessed into the back of the slide, and having a semicircular groove upon its front face, the depth of this groove gradually diminishing so that its bottom forms an inclined plane, against which the end of a pin works, which is carried by a flat flexible spring covered with velvet. By turning the disc round with the fingers, the pin and with it the spring is forced outward against the back of the sensitised plate, which is thus pressed forward to the desired position.

After exposure the sensitised plate is returned to the bag, the open end of which is again folded down and held by the elastic band, and it can then be safely removed from the dark slide.

When sensitive plates of large size are to be used, it is preferable to make the bag contain one such plate only.

The improved changing bag may be adapted to any existing dark slide, upon which it is only necessary to provide a groove to receive the metal frame at the mouth of the bag in the way described.

In order to be able to use sensitive plates of different sizes in the same dark slide, separate frames of corresponding sizes are provided, either of which can be fitted into the dark slide itself.

Each of these frames is open below, and is provided with a groove or guide to receive the metal frame at the mouth of the flexible bag in the way described.

By this invention considerable saving in weight, space, and cost is effected.

AN IMPROVED MAGNESIUM LIGHT FOR PHOTOGRAPHIC PURPOSES.

No. 7035. JOHANNES GAEDICKE, 74, Ritter-strasse, Berlin, and ADOLF MIETHE Potsdam.—*May 13, 1887.*

OUR invention relates to an improved magnesium light for photographic purposes, and has for its object the removal of those difficulties which have hitherto prevented the general adoption of the same for photographic purposes, notwithstanding that its eminent value as an artificial source of light is generally recognised, in fact, experience proves that for momentary photographs or pictures produced in a fraction of a second it is a valuable substitute for either the electric or day light, but for several reasons these advantages could not be turned to practical account. This may be explained by the fact that it has been the practice hitherto to burn the magnesium in lamps, in the form of thin ribbon or wire, but it was found to be a most difficult matter to determine the proper "exposure." Another difficulty arose in the burning of the wire itself, as neither the method above mentioned of burning the wire in lamps, or of burning the same uncovered, proved suitable for employment in the *alder* for several reasons, amongst others, that the latter portion of the wire was not consumed rapidly enough, that the wire was with difficulty ignited, but more especially because the products of combustion were afterwards to be disposed of. The action of the dazzling rays of the magnesium light on the object was, however, a sufficient reason why the same was not employed for photographic purposes. The various improvements invented for the purpose of removing these difficulties have not attained the desired result. According to our invention the magnesium is no longer used in the form of a thin ribbon or wire, but as a fine powder which is mixed in a certain proportion with other bodies, which readily give off oxygen (known to intensify the magnesium light), and also simultaneously mixed or amalgamated with such bodies as accelerate the combustion of the mixture. Such substances or bodies are, for example, chlorate of potash, prussiate of potash, sulphurous and other combustion materials. Whereas prussiate of potash exceedingly accelerates the combustion, the chlorate of potash, on account of its containing a large amount of separable oxygen, performs the very essential function of increasing the temperature to such an extent that the radiating light and the action of the magnesium is greatly intensified. The combustion of the mixture specified in the present specification lasts from about one-thirtieth to one-fiftieth of a

second. It must here be remarked that although the magnesium light, prepared according to our invention, possesses several hundred thousand candle-power, yet it is not possible for the effect of a flash to be so powerfully felt that a reaction of the "model" could take place.

This is explained by the fact that the time the flash takes to find its way from the sensitive nerves to the central organ, and from thence back to the operative nerves is much longer than the limit given above for the burning of the powder, and even if the "model" should move, this movement could only have taken place after the photograph or picture was already taken or completed. Our said improved magnesium powder or mixture is of great value for the purpose in question, because the burning of the same when ignited takes place without any explosion whatever, expanding gases not being objectionably produced. The rapidity of combustion depends considerably upon the fineness of the magnesium powder and other ingredients, and also upon the degree of their mechanical intermixture. The most suitable mixture for this purpose consists of:—Twelve parts of chlorate of potash, six parts of magnesium powder, one part of prussiate of potash; or, twenty-four parts of chlorate of potash, twelve parts of magnesium powder, one part of amorphous phosphorus.

The chlorate of potash is first pulverised in a suitable mortar, and the other substances, namely, the magnesium powder and prussiate of potash, then added. The best results are attained by mixing the substances together upon a smooth sheet of paper by means of a wooden or horn spoon, or by rolling the substances together until a fine grey powder is produced, which serves thus for the magnesium light. The magnesium powder so prepared can be ignited by means of an electric or other spark, and burns with a short flash. By selecting a suitable method of burning the magnesium powder, a light may be produced which can be employed to great advantage for other purposes, besides those of instantaneous photography. Our latest experiments have proved that the introduction of substances or bodies, which show certain coloured lines in the spectrum of the Bunsen burner, make the magnesium light much more effective for these colours. For these reasons we provide the previously described magnesium mixture with an addition of sodium, strontium, lithium, calcium, tellurium, barium, and other salts, in order that the magnesium light thereby produced may be made more effective for yellow, red, or green colours. The proportion of these additions of light colouring bodies can be varied from a minimum quantity upwards, to about ten per cent. of the mixture, but it is not advisable to take a larger quantity because they would affect the temperature of the combustion, and also decrease the effect of the light.

Having now particularly described and ascertained the nature of our said invention, and in what manner the same is to be performed, we declare that what we claim and desire to secure by letters patent is:—1. The employment of a mixture of magnesium powder with oxygen yielding salts, as for instance chlorate nitrate and other salts, as well as with substances that accelerate the combustion such as prussiate of potash, amorphous phosphorus, sulphurous and other combustible materials, pine soot, &c., for instantaneous photography and for producing a momentarily intense light, substantially as described in the foregoing specification. 2. The employment of light colouring substances, or bodies in connection with the herein-described magnesium light in order to make the light more effective for the corresponding colours, substantially as described in the foregoing specification.

[We never like, where it can be avoided, to throw cold water upon a patent; but it is probable that the patentees in this case had never read an article, in our issue of May 24, 1867, entitled, *Photography by a Flash*, from which we here make a brief extract: "Mr. Skaife finds in magnesium powder, when mixed with other pyrotechnic compounds, the means of obtaining a flash of light of the desired intensity and brevity. At the meeting of the South London Society in November, 1865, we ignited a powder composed of magnesium, chlorate of potash, and sulphur, by which we had been able a few evenings previously to obtain a sharp image of a print while it was being slowly moved." This, we imagine, settles the fate of the foregoing patent.—EDS.]

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
August 1	Notts	Institute, Shakespeare-street.
" 2	Coventry and Midland	Coventry Dispensary.
" 2	North London	Myddelton Hall, Upper-st., Islington.
" 2	Glossop Dale	Society's Rms., Norfolk-st., Glossop.
" 2	Holmfirth	
" 2	Sutton	Society's Rooms, 18, High-street.
" 2	Sheffield	Masonic Hall, Surrey-street.
" 2	Bolton Club	The Studio, Chancery-lane, Bolton.
" 3	North Staffordshire	Mechanics' Institute, Hanley.
" 3	Photographic Club	Anderson's Hotel, Fleet-street, E.C.
" 4	London and Provincial	Mason's Hall, Basinghall-street.
" 5	Halifax Photographic Society	M. Manley's, Baram Top.
" 5	Yorkshire College	

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

Last Tuesday night, at a meeting of the above Society, held at 5A, Pall Mall East, London, Mr. William England, Vice-President, occupied the chair.

Mr. JACKSON said that the Eastman Company had just been developing about eighty half-plate film negatives taken by Mr. Walker at the Convention at Glasgow.

The CHAIRMAN had seen views of Venice containing little mottled markings, perhaps the grain of the paper.

Mr. E. COCKING had been perplexed by obtaining negatives which were not sharp, although the image on the ground-glass had been perfectly sharp; negatives taken in the middle of the day had this defect, and not those taken in the evening.

Mr. W. M. ASHMAN remarked that heat had a physiological effect upon some persons, causing them to see less perfectly in the middle of a hot day than in the evening.

Mr. AYRES found that blue tinted spectacles were a help in focussing sharply; they made the blacks of the image look blacker.

The CHAIRMAN had had the same experience.

Mr. W. F. DONKIN had had a little experience with American stripping films. If the directions were not closely followed the operator might go entirely wrong. The negatives must not be left too long in water or upon the collodionised glass.

Mr. JACKSON said that they must be left long enough in water, but not too long; glycerine and methylated spirit added to the water facilitated working.

Mr. W. E. DEBENHAM asked if the permanency of prints upon bromide paper was an established fact, for he saw that the Society had issued a statement to that effect upon a print issued with the last number of its *Journal*. He would express no personal opinion as to the permanency of such prints.

Mr. SAMUELS remarked that the *Journal* said that the prints had been presented by Messrs. Morgan & Kidd, and he thought that covered the point.

Mr. DEBENHAM asked if that meant that when any dealer issued a print by any particular process he might also issue with it, apparently under the seal of the Society, any printed statement about it he chose.

Mr. COCKING said that the prints as mounted were not received from Messrs. Morgan & Kidd until the day before the *Journal* was published.

The CHAIRMAN thought that the statement should not have been printed upon the card.

The HON. SECRETARY said that Mr. Debenham was quite right. The issuing of the statement was a slip. In reply to a question whether he would have stopped the issue had he seen the prints beforehand, he said that the inquiry related to the editor's business.

Mr. COCKING exhibited a rack made by Mr. Hinton in which to wash plates. Its construction cannot be explained without the aid of diagrams.

The CHAIRMAN remarked that it would take plates of different sizes, that it was ingenious, and that its principle of construction was new to him.

Mr. Freshwater exhibited some instantaneous views of the Jubilee procession.

Mr. COCKING exhibited Newman's shutter.

Mr. ASHMAN spoke of Mr. Van der Weyde's photograph of Miss Mary Anderson at the American Exhibition; it stood out stereoscopically like a statue.

Mr. DONKIN had not seen it, but it was solely due to getting rid of the impression of flatness by viewing through a tunnel. If a good photograph were viewed through a tube with one eye, so as to cut off surrounding objects, the image would appear to stand out solidly.

Mr. ASHMAN thought that photographs nowadays did not stand out so stereoscopically as when the tunnel studios were in use; might it not be well to return to that form of studio?

Mr. DEBENHAM was of the same opinion. Whenever he had not to place the camera very near the sitter he always used a tunnel; it was movable and ran upon wheels.

Mr. SAMUELS had found a camera with a long hood to produce pictures having a more stereoscopic effect than obtainable with his other cameras; no doubt the hood acted as a tunnel, cutting off much useless stray light.

It was announced that at about the end of the autumn an evening would be devoted to the exhibition of reflecting and other stereoscopes and of stereoscopic slides, also that a discussion would take place thereon.

The meeting then broke up.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday, July 21, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. H. M. Hastings presided.

Mr. J. B. B. Wellington exhibited views taken in Scotland with Watson's defective camera while it was held under his arm.

Mr. L. Medland exhibited composition photographs printed as election skits.

Mr. A. L. HENDERSON said that Mr. Rockwood, of New York, had called upon him on his way to Paris and told him about an American shutter, one end of which took in the end of the lens inside the camera; at the other end was a slit the full width of the plate, and which fell near the plate, thus giving the exposure; the shutter was somewhat the shape of an egg inside the camera. The late Mr. Collins had given him a shutter made on somewhat the same principle.

Mr. W. E. DEBENHAM remarked that the most satisfactory shutter which he and his brother had ever used consisted of a spring blind near the plate; the blind had a large opening. It operated in one-thirty-fifth of a second, as measured by Mr. A. Haddon.

Some members remarked that Mr. Worrall and Mr. Edwards had constructed shutters upon that principle.

Mr. J. J. BRIGNSHAW had found Place's shutter to be simple and effective.

Mr. HENDERSON said that Place's was the most light-tight shutter he had ever seen; many of the shutters which work between the lenses did not lap over the lens mounts sufficiently to totally exclude light, so fogging then became merely a question of time.

Mr. MEDLAND spoke well of Newman's shutter.

Mr. HENDERSON had been copying a picture with a portrait lens, and was puzzled, after exposing several plates in succession, to find an effect in each of them as if the centre of the picture only had moved during the exposure. He afterwards found a small opening admitting light out of the field of view of the lens and in the guides for the diaphragm; on stopping this opening the effects disappeared. It was an experiment which could be repeated at any time.

A question in the box asked the best way of evenly coating paper with emulsion.

Mr. W. H. PRESTWICH said that a few weeks ago a good plan devised by an American had been reprinted in one of the English photographic journals; sheets of paper soaking in hot water were removed one by one and laid upon warm glass, then coated with emulsion.

Mr. A. COWAN remarked that the finest coating of emulsion which could be given to small sheets was applied in a rather troublesome way; glass was first coated with the emulsion, paper was then squeegeed down upon it, the whole left to dry, and the coated paper then stripped from the glass. The glass had to be prepared in the first instance, otherwise the emulsion would stick to it and would not strip.

Mr. HENDERSON had heard that Mr. Hubert had received some royal patronage recently; he hoped he would exhibit his work in relation thereto to the Association.

Herr HUBERT remarked that he would do so on a future occasion.

The HON. SECRETARY had seen many detective camera pictures lacking in sharpness; the detective camera photographs he had seen most free from this defect had been taken by Mr. W. England with the camera fixed to his tricycle.

Mr. WELLINGTON remarked that that method of fixing the camera gave an advantage.

Mr. HENDERSON thought that a 1b portrait lens would be good for detective cameras.

Mr. W. M. ASHMAN called attention to a statement in the *Photographic Times* of New York, that slight fog in a negative could be cleared away by a ten per cent. solution of ammonia iron alum, which would also give intensification if the negative were left in long enough. He had tried it, and found that in time the image vanished entirely under the recommended treatment.

Mr. HENDERSON asked if the negative contained traces of hypo.

Mr. ASHMAN had tried one negative before it was fixed and another after it had been fixed and washed; in both instances the picture vanished.

The meeting then broke up.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE Committee of this Association met on the 21st instant.

The minutes of the previous meeting having been read and confirmed, Messrs. R. H. Callaghan, A. E. Ewen, F. T. Lupton, H. C. Roberts, J. B. Stokes, J. P. Turnbull, and Miss Godfrey, were elected members of the Association.

Mr. J. J. BRIGINSHAW reported the action taken by him at the Convention re the Association, the result being of a satisfactory character.

Other details of business having been dealt with, the meeting terminated.

AMATEUR PHOTOGRAPHIC ASSOCIATION.

A COUNCIL meeting of this Association was held on Thursday, the 14th instant, at the offices of the Association, 12, Old Bond-street.—His Highness the Duke of Teck in the chair.

The minutes of the last meeting having been read and confirmed, the following members were elected:—The Earl of Kilmorey, Dr. Drew, Alfred Mulholland, Esq., Hamilton Emmons, Esq., Colin Boyd, Esq., and F. Gowan, Esq.

The HON. SECRETARY (Mr. Arthur James Melbush) then laid before the meeting copies of all the pictures contributed for the current year, and Mr. GLAISHER (Vice-President) read his report, in which, after congratulating the meeting on the exceptional excellence of the contribution for the present year, stated that there were in the First Class 138 pictures contributed as follows:—C. Stephens, 7; The Right Hon. the Lord de Ros, 3; R. Murray, 1; W. S. Hobson, 8; Major Board, 3; General Sladen, 3; R. O. Milne, 11; W. Vanner, 9; W. Muller, 9; R. Leventhorpe, 15; George Brook, 9; F. H. Shaw, 3; Colonel Biggs, 4; The Right Hon. the Earl of Rosse, 1; A. Tagliaferro, 4; L. F. Reichling, 5; H. E. White, 7; Miss Mary Egerton, 2; Mrs. Hobson, 14; W. Gaddum, 6; Miss Jane Wilson, 2; Mrs. Coats, 1; J. C. Cohen, 2; C. F. Pritchard, 3; W. Sculthorpe, 1; The Hon. Kingsly Bethell, 2; Baron Liebieg, 3; and H. Emmons, 1.

The Second Class contained 109 pictures, the remainder of the pictures being comprised in Classes 3, 4, and 5.

After some discussion as to whether the first prize should be adjudged to Mr. H. E. White or to Mrs. Hobson, it was decided in favour of the former, and the following prizes were awarded:—

To H. E. White, Esq., the first prize, a large silver goblet, for Nos. 159 and 2633. Mrs. Hobson, the second prize, a silver goblet, for Nos. 38, 42, 43, and 45. W. Muller, Esq., a water-colour drawing in frame, for Nos. 1002 and 1007. George Brook, Esq., a silver goblet, for Nos. 5, 7, and 10. R. Leventhorpe, Esq., a silver goblet, for Nos. 141, 147, and 155. W. S. Hobson, Esq., a water-colour drawing in frame, for Nos. 334, 336, and 337. R. O. Milne, Esq., a portrait album elegantly bound, for Nos. 15 and 16. W. Vanner, Esq., a water-colour drawing in frame, for Nos. 90 and 91. Baron Liebieg, a portrait album elegantly bound, for No. 3. W. Gaddum, Esq., a landscape album elegantly bound, for Nos. 4 and 7. And to Lord de Ros, a portrait album, for No. 8 and a series of Views at Bath. Certificates of honourable mention were awarded to General Sladen, Major Board, F. H. Shaw, Esq., Colonel Biggs, A. Tagliaferro, Esq., L. F. Reichling, Esq., and C. F. Pritchard, Esq.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual bi-monthly meeting of this Society was held on Tuesday, the 19th instant, at Myddelton Hall, Islington.—Mr. J. Traill Taylor, President, in the chair.

The minutes of the previous meeting having been read and confirmed, the President showed some large silver and platinum prints of groups from negatives taken at the Photographic Convention of the United Kingdom by Mr. John Stuart, of Glasgow, and Mr. Richard Keene, of Derby, at Tarbert and Craig Millar Castle.

Mr. F. W. COX inquired the best method of obtaining a reduced print from a large one.

The PRESIDENT replied that he should make a reduced transparency on glass from the original negative, and then by contact printing obtain the reduced negative.

The President being compelled to leave in consequence of having to attend an important meeting in another part of London, Mr. Cox was voted to the chair.

Mr. William Swan was elected a member of this Society.

The CHAIRMAN thought the members would like to hear from the Hon. Secretary a brief report of the proceedings of the Convention.

Mr. H. M. SMITH said that he and a few others travelled to Scotland by boat, and were well repaid for the extra outlay of time by the opportunities which presented themselves in the river and also on board for instantaneous shots. He then gave an account of the various excursions and evening meetings, and stated that he considered this Convention had been a very great success, being attended by two hundred professional and amateur photographers, representing twenty different Societies in the United Kingdom. He also spoke in terms of the highest praise of the manner in which the members had been treated by their Scotch brethren, especially of the kindness and hospitality of the Edinburgh Society.

Mr. H. Walker showed some prints from negatives taken at Chigwell.

Mr. A. P. HIGGINS showed one of Tylar's metal dark slides, and stated that he found them work well, the only disadvantage being their great weight. He also showed two mahogany half-plate double backs which had been purchased the one for 6s. and the other for 7s. 6d., the latter having a hinged shutter.

The HON. SECRETARY warned members from purchasing cheap photographic materials without exercising the greatest care in examining them before parting with their money. In the case of the two shutters passed round by Mr. Higgins, they must be far from light-tight, and he demonstrated this fact by pushing two thicknesses of note-paper into the slides while closed.

The CHAIRMAN remarked that it would be impossible to exclude light from such shutters unless the greatest care was taken with them. In his opinion, the American form, where the shutter was entirely removed from the slide in making the exposure, was the best.

The HON. SECRETARY, referring to the proceedings of the previous meeting, said that he had been trying one of the "right-about-turn" form of shutters, but could not succeed in obtaining a sufficiently quick exposure with it, and was now using a plain drop shutter accelerated by elastic bands. He had had an opportunity of examining Mr. C. Wollaston's diaphragmatic shutter, and considered it both practically and theoretically perfect, and would endeavour to obtain the loan of one to show at the next meeting.

The CHAIRMAN did not think there was any necessity for very elaborate shutters. Exposures up to one-fiftieth of a second could be made with the plain drop shutter, and in his opinion there was nothing better, and there was no mechanism to get out of order.

A discussion ensued upon the best method of packing plates for travelling.

The CHAIRMAN said he always repacked his plates after being exposed in the same manner as they were originally packed by the maker, and had never had the misfortune to break any.

Mr. READER recommended packing the plates with pieces of white blotting-paper between them.

The HON. SECRETARY said he always packed his plates after exposure in a solid block face to face, and had never broken or damaged any, but in carrying plates as packed by the makers before exposure he had often had the misfortune to find as many as two or three plates broken in one box.

Mr. READER inquired whether any member could give his experience of developing plates away from home.

The CHAIRMAN and Mr. J. HUMPHRIES both thought it a mistake to develop away from home unless it was simply a trial plate.

The following excursion was then arranged:—July 30, to Wanstead Park: train from Liverpool-street (Great Eastern Railway) at thirty-five minutes past two p.m.

The members will also join in an excursion to Dorking with the Photographic Club on Monday, August 1. Train from London Bridge at fifty minutes past ten a.m.

Correspondence.

All Correspondents should never write on both sides of the paper.

THE LATE PHOTOGRAPHIC CONVENTION.

To the Editors.

GENTLEMEN,—May I venture to ask if we shall have any further reports of the discussions on the papers read at the above Convention at Glasgow? I feel sure from the number of the papers and the representative gathering present an immense amount of useful information must have been given in the various discussions, and I cannot but think it a pity that members who were unavoidably absent, and the photographic world in general, should lose the benefit to be derived from their perusal. Cannot something be done even now to rectify the omission?

While writing, I should like to make some suggestions in reference to future meetings of the Convention. Could not the subscription be increased so as to enable the Executive to publish regular proceedings, the same as is done at other meetings of a similar kind? Judging also from what several friends who attended the Convention told me, I should think it would be advisable to devote separate days to the reading of papers and the outings, as the proper enjoyment of one, if not of both, must suffer when they are taken on the same day. Of course this arrangement was unavoidable at the meeting at Derby last year, when the period fixed was three days, but now the time has been extended to six days, there should be no difficulty in keeping the objects of the Convention distinct, and I certainly think one day, if not more, should be given up to the reading and proper discussion of papers, if only as an act of courtesy to the authors who have devoted time and labour in preparing them.

Expressing my gratification at the way the Derby child has grown in proportions and usefulness, and with every good wish for its future advancement—I am, yours, &c.,
H. M. HASTINGS.

54, Edith-road, West Kensington.

[We do not think that there is any chance of there being further reports of the discussions on the papers read at the Convention. We are entirely at one with Mr. Hastings as to the desirableness of effecting a separation between the excursions and technical proceedings, but Glasgow and its vicinity are so exceedingly rich in everything allied to scenic grandeur that it was difficult to arrange matters otherwise on last occasion. While it is undesirable to increase the subscription, yet do many feel that an annual subscription of five shillings is too low.—Eds.]

THE "EURYSCOPE."

[By request of Messrs. Marion & Co., the agents for Messrs. Voigtlander & Son, we insert the following letter, addressed to them by the eminent firm of opticians.]

"Braunschweig, 18 July, 1887.

"Messrs. MARION & Co., London.

"DEAR SIRs,—We duly received your favour of the 16 July. The advertisement of Perken, Son, & Rayment, you sent us has greatly astonished us. We assure you and state herewith, that we are the first opticians who invented an objective named 'Eurycope,' the construction of which we published already in 1877, as every handbook of photography will confirm. The name 'Eurycope,' too, is at first employed by us; until this day nobody has dared usurp this name, which we consider to be ours. How such a proceeding is to be judged, every honest man knows and is unnecessary to say.

"That furthermore Messrs. Perken, Son, & Rayment put the words 'None genuine unless bearing Trade Mark' in their advertisement of their imitated construction is only intended to deceive the public and to mask the design. In the interest of all the photographers and amateurs we hope that they will not succeed in their manoeuvres.

"We shall be much pleased to hear soon again from you in this matter—and remain, Dear Sirs, yours very faithfully,

"VOIGTLÄNDER & SOHN."

STRIPPING FILMS.

To the Editors.

GENTLEMEN,—I make a suggestion to my amateur friends who are engaged in solving the practical difficulties of stripping films. Last year I brought before the Birkenhead Photographic Society specimens of transferred albumenised films taken thirty years ago, and as good now as the first day they were completed.

In the days of the wax paper process we placed the sensitive waxed paper in a bath of casine, or what is commonly called whey. We found it increased the sensitiveness of the waxed paper. The idea was adopted by a maker of albumenised paper, who rashly rushed into the market with paper so prepared, and to his horror the film invariably separated from the paper support whilst in the process of fixing with hyposulphate of soda.

I transferred a number of films on to paper and opal, but was obliged to give it up as the maker of the albumenised paper would not continue his mistake. The film when transferred was remarkably tough and stood any amount of handling; when strongly printed the definition was as fine as any transparency on glass. The print left on the paper was of a spongy appearance and useless as a photo.

Could we not persuade the Eastman and other negative paper makers to try the whey experiment before coating their paper with the emulsion? I feel confident it would add to the sensitiveness of the emulsion film, whilst it would render the transference of it to glass or paper more easy and certain.

Any plan that would reduce the operosity of the process as at present carried on is desirable, for undoubtedly not only is the beauty of the negative enhanced, but the charm of portability is perfected.

Birkenhead, July 27, 1887.

JAS. ALEX. FORREST.

"MERIT" AND "MEDALS" AT DERBY EXHIBITION.

To the Editors.

GENTLEMEN,—When an exhibition prospectus distinctly holds out to exhibitors that certain awards are to be made, is it the right thing that at the pleasure of the judges they can withhold any of these awards, taken for granted, of course, that there are a sufficient quantity of pictures exhibited? This would seem to be the rule at the Derby Exhibition, and when asked why the promised awards were not made, the answer received is, that the judges did not see sufficient merit in the pictures shown to warrant any further awards being given! Now, I ask, is it not decidedly unsatisfactory, after making a distinct statement with regard to awards, and putting exhibitors to no end of trouble and expense in sending their exhibits, that they have to pass through some unknown merit ordeal? And what I would like to know, through the medium of

your valuable JOURNAL, is, what is this standard of merit through which they have to pass? Are the judges supposed to know all the circumstances under which every individual photograph is taken? Is it the most gorgeous landscape that gains the medal? or the most spacious mansion? or the photograph of a titled lady? or an actress in a blaze of white? or a something big and showy to the eye, with a month's retouching upon the negative, and other aids outside the pale of true photography?

Is it not a fact that gainers of the medals at photographic exhibitions of the present day are, as a rule, those men who can command a range of lenses and apparatus that would make a provincial photographer's teeth water, and have a staff of assistants, through whose hands their pictures pass, that it becomes almost impossible to know to whom the real honour of the medal belongs? Now, I, a provincial photographer without the aid of a large range of lenses, or even a single assistant, have had the daring to send two years in succession to the Derby exhibition, exhibiting both seasons in the architectural class, and have found that the first season, although three awards were promised, none were made, and that this year one medal has been withheld. I am not particularly interested to know how far I may be removed from the medal list, but I am anxious to know why there is still a gap left in prize list, and it is this standard of merit that is bothering me.

Now I would suggest that in future the Committee of Management of this Exhibition should say in their prospectus that any or all of the medals may be withheld provided the pictures do not come up to the standard of merit, and so keep unsuspecting photographers like myself from supposing that the best pictures exhibited at Derby Exhibition would receive the awards and not the best pictures the world can produce which may not be shown at that particular exhibition.—I am, yours, &c.,

Arbroath, July 26, 1887.

J. GEDDES.

CHERRY FABRIC AND RED LIGHT.

To the Editors.

GENTLEMEN,—I suppose most photographers who have used cherry fabric know that it loses its colour. The enclosed might be called a good specimen of fading, having become almost white where exposed to light.

I believe many injure their eyes by having red light right down to the level of the developing dish, so that the glare of red strikes directly into the eyes. I find I see better, and with much less discomfort to my eyes, by darkening all the lower portion of my window, so that all the light falls from above the level of the top of my head. I would recommend those who have red or yellow light down to the level of their developing dish to try this.—I am, yours, &c.,

H. G. M. CONYBEARE.

The Hut, Ingatstone.

IRIDESCENT MARKINGS ON PLATES.

To the Editors.

GENTLEMEN,—I notice from reports of Societies' meetings that the question, "What can be done to remove the iridescent markings around the edges of plates?" has been often asked lately.

I have carefully tried the prescribed remedies, but found them all fail. The red prussiate of potass and hypo reducer removes them almost instantaneously if applied while the negative is still wet. Of course when using this it is necessary to carry the development a little further than usual to counterbalance the action of the reducer. By this treatment plates otherwise quite useless may be made to give good negatives.

Doubtless you will find many people who know all about it, and have used it for years. I have not seen it in print, and trust it may prove useful to some of your readers.—I am, yours, &c.,

J. P. GIBSON.

Hexham, July 23, 1887.

FINDERS AND FOCUSERS.

To the Editors.

GENTLEMEN,—In reply to "Jumelle's" inquiry, I beg to say that at the proper time he and all others will know all about my special claim in connection with the finder and focuser.

Let "Jumelle" moderate his sorrow; he will find that I have not done so silly a thing as he supposes.—I am, yours, &c., S. D. McKELLEN.

Manchester, July 22, 1887.

Exchange Column.

* * No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Half-plate rectilinear lens for quarter-plate bellows camera with three double backs, by good maker.—Address, E., 11, Maury-road, London, N.

I will exchange a whole-plate portrait lens for enlarging apparatus with six-inch condensers.—Address, W. W., 156, Noel-street North, Nottingham.

Wanted in exchange, a good portrait lens for pictures not less than ten-inch or good studio furniture. See Sale Columns.—Address, J. PICKER, Runcorn.

Wanted, McKellen's or Shew's combination (Brown's patent) whole-plate camera in exchange for lever watch and cash.—Address, BERNARD GREEN, Cockermouth.

I have a number of carbon enlargements by Vernon Heath (views, &c., 27 x 23); will exchange for outdoor apparatus.—Address, W. SLATER, 232, Albany-road, Camberwell.

Answers to Correspondents.

PHOTOGRAPHS REGISTERED:—

Lady Dalton Fitzgerald, 33, Grosvenor-place, S.W.—*Photograph of Buckingham Palace.*
P. M. Laws & Son, Newcastle-on-Tyne.—*Photograph of the prize bull "Rob Roy."*
G. W. Wilson & Co., Aberdeen.—*Oil painting of Dorothy Vernon.*

C. BANYARD.—Try No. 2.

S. J.—If you find the paper tones better with the borax bath than with the acetate, why not continue to use it?

H. B. H.—1. Under the conditions the occurrence is by no means singular.—2. There is no remedy now unfortunately.

L.H.—Lantern pictures may be produced from paper negatives, but care must be taken not to allow the grain of the paper to show.

W. J. (Doncaster).—Hardwich's *Photographic Chemistry*, ninth edition, published by J. & A. Churchill, New Burlington-street.

B. A. WESTON asks us why he cannot dissolve gelatine in methylated spirit.—The answer is very simple. It is because gelatine is not soluble in spirit.

H. G. M. CONYNGARE.—Fruit and vegetable presses or strainers have long been employed in breaking up emulsions. The special one referred to will answer quite well.

X. Y. Z. (Hyde).—For ordinary landscape work the plates mentioned are well adapted. Better sacrifice one or two small ones at first in order to ascertain the most suitable exposure.

J. C. B.—We obtain our asphaltum from a drysalter in Long Acre. It dissolves readily in benzol and other solvents. It can, doubtless, be obtained in solution from artists' colourmen.

BUCKS.—The platinotype process will answer all your requirements, and it is simple to work. If you mask the negatives neatly you can print the pictures with a margin, which enhances the effect.

P. P.—The light of a common paraffine lamp is quite strong enough for printing on bromide paper. You must take the precaution to expose at some distance from the light, or there will be risk of over exposure.

J. W. HANDLE.—We know of no one in this country from whom you are likely to obtain Laudy's work on the lantern unless J. J. Atkinson, Manchester-street, Liverpool, who keeps several American productions.

QUIZ.—1. We do not know how the sulpho-pyrogallol referred to is prepared. The manufacturers do not publish the formula by which it is made.—2. Dumfries.—3. There is nothing better than the hyposulphite of soda.

GEORGIUS would be glad to know why he gets scratched lines on some of his prints when burnishing. He does not think the burnisher is at fault, as it is quite new.—If the scratches do not exist on the bar of the burnisher, they are probably caused by grit or dust being on the prints at the time they are burnished.

J. D.—1. The print is not toned.—2. Employ an intense negative and a good toning bath of your own making; do not buy one ready made.—3 and 4. Yes.—5. The lens is right enough; all depends upon the skill of the user.—6. We do not know.—7. Yes, if dry ferrotype plates are employed, but they are usually made by the wet collodion process.

RICHARD W. says he lent some negatives to a friend to try his hand at printing with, and when they were returned many of them were badly scratched. He asks if there is any remedy.—The only plan is to touch out the scratches with water colour. This must be neatly done, otherwise the blemishes will become more conspicuous than if they were left alone.

LOLO.—The soda to employ in the developer is not the bicarbonate, but *washing soda*. The white dry powder with which the crystals get encrusted is better than the crystals themselves. In such cases where bicarbonate is procurable and the monocarbonate or washing soda is not, the former then may be made to answer by placing it in an iron ladle or spoon, or on a shovel, and heating it to an approximate redness.

PERPLEXED wishes to know the methods used for printing the "titles" of views on negatives so as to appear in white letters in the prints.—The plan usually adopted is to write the titles (backwards, of course) on the negatives with an opaque ink or paint; it will then appear white on the print. The writing should be done with a fine sable pencil. Bates's black varnish to which a little lampblack has been added forms a capital ink, as it does not run and dries quickly.

A. WARD says: "I have a few ounces of triple crystallised nitrate of silver which I have had by me since I used to work with collodion, and the crystals look discoloured and different from the fresh nitrate. Is it necessary to recrystallise it before it is used for sensitising paper?—It is not at all necessary to do anything with the salt; the crystals being slightly discoloured is of no consequence. Crystals of nitrate of silver, if neutral, are very prone to discolour by keeping, particularly if exposed to light.

STEPHEN WILLS writes as follows: "I have been making some prints on gelatino-bromide paper with the glazed surface, and wanted them with a high gloss, like enamelled prints. I squeezed them on to glass, and when I took them off they had all the gloss I desired, but when they were mounted it all disappeared and were nothing the better for being on the glass. What shall I do?"—To retain the highly glazed surface, the mount should be attached to the print while it is yet on the plate and not stripped until it is perfectly dry.

C. W. P. inquires: "What part of the Isle of Wight would you recommend as being the best to visit from a photographic point of view—a place where rural scenes could be secured together with the ordinary seaside views? Reading so much about 'chalk cliffs' and 'downs' has frightened me."—Fine pictures may be secured in, and in the vicinity of, Shanklin Chine, but Ventnor and all along that coast will also permit a few dozen plates to be exposed with advantage. For yachts and boat scenes Cowes is unrivalled; but, in fact, go where you like in that island, innumerable pictures are to be found.

W. ETHELBERT HENRY (Sarina, Ont.).—The firm with whom you have had dealings is a totally different one from that referred to by the Queensland correspondent. We have put ourselves to the trouble of inquiring into the grievance of which you complain; and having been favoured with a perusal of the whole correspondence, including copies of letters sent to you and your friends, have no hesitation in saying that your allegations of inattention and discourtesy have not the slightest foundation in fact, as we have now before us copies of the letters (torn from the letter book) that were sent you. We imagine they may have miscarried in course of post, but the firm named could not possibly have shown more attention than was done.

H. C. M. writes: "I am going to take a trip to the West of Ireland in about a fortnight, taking with me a half-plate camera; in using that camera for taking stereoscopic views on, say, quarter-plates, could you tell me what distance to shift the camera for the second exposure? also if the angle of view embraced by the lens would need to be taken into consideration?"—In reply: The camera must be shifted to such an extent as to exceed slightly in the two positions of the lens the distance apart of the eyes. The greater the separation the more pronounced will be the stereoscopic effect of the pictures, although such will not then be true to nature, but exaggerated. This holds good altogether irrespective of the nature or focus of the lens or the width of angle it includes.

W. writes: "I have a quantity of glass remaining from the days of the collodio-albumen and wet processes, in various sizes from quarter-plate up to 18 x 14, which is now, under the present system of commercial gelatine plates, of no use to me. The bulk of it is in the smaller sizes. I have not offered it to any of the dry plate makers, as I understand they prepare their plates in large sizes and cut down to the required dimensions after coating, and that the smaller sizes would be too much trouble for them to cut single plates. I should be very much obliged if you could inform me how to dispose of it to the best advantage, as at present it is merely useless lumber."—We imagine that hundreds of photographers are in the same position as our correspondent with reference to a stock of useless glass. The only plan we can suggest is to advertise it for sale, though we have doubts if it will meet with a purchaser. We know many photographers who would be glad to give away their old glass if they could meet with any one who would accept it.

MR. GEORGE P. CARTLAND writes: "In reference to your remarks on 'Jubilee negatives and pictures,' I should like to ask you if you think that a picture similar to the one accompanying this letter could have been obtained on a wet plate at eight o'clock in the evening, as this was done?"—The photograph referred to is a scene at Windsor, taken on the occasion of the Queen's arrival. By the ordinary wet collodion process it could not have been done unless with a lens of unusual angular aperture. But Mr. Cartland's lens has been somewhat strained, for while the centre and the nearer right side is sharp, the left, in which the royal carriages are drawn up, is rather out of focus. This doubtless might have been obviated by a more vigorous application of the side-swing. But the picture is a good one notwithstanding.

We hope next week to overtake arrears of notices of exhibits at the Convention and in the Manchester Jubilee Exhibition.

We inadvertently applied the wrong name to the principal figure in the cartoon of which we spoke last week. It should have been Joseph, not "John," Gray.

A PROPOSED trip in the s.s. "Ceylon" to the Baltic, Russian and Scandinavian capitals. Will some one give hints as to the best guide-book useful to a photographer, or any other information?—C. V.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting, August 3, 1887, will be on *Colour Photography*. Bank Holiday outing at Dorking: train from Victoria at thirty minutes past ten.

The next meeting of the North London Photographic Society will take place on Tuesday, August 2, when Mr. Octavius Smith will read a paper on *Systems of Numbering Photographic Slips and Lenses*. Visitors are invited.

We learn with regret that the rear portion of the photographic store of Messrs. E. & H. T. Anthony, New York, was destroyed by fire on the night of the 12th instant. The chemical and apparatus factories in the front store were uninjured.

It is now some time since we had an opportunity of making trial of dry plates of American manufacture; but during the past week a sample packet, bearing the "Eagle" brand, has been left with us by Mr. Donelan from New York. We have tried them and find them to be both quick and good—quite as good, in fact, as many plates of English manufacture.

We are always glad to receive specimens of photography executed in distant parts of the world. Mr. A. Farsari, of Yokohama, Japan, favours us in this respect with some of his works illustrating Japanese life and character. Mr. Farsari says he has taken up photography but a short time ago, yet are his works most creditable productions, some of them being skilfully coloured and tinted. They compare very favourably with home productions.

No. 1422. VOL. XXXIV.—AUGUST 5, 1887.

IRON ALUM AS AN ALLEGED INTENSIFIER.

THE latest claimant for popular support as an intensifying agent comes forward in a somewhat anomalous character, since it is said to clear away slight fog, and, at the same time, add to the density of the negative. But in the brief discussion that took place on the subject at the last meeting of the London and Provincial Photographic Association, Mr. Ashman, who had tried ammonia-iron alum, found that, so far from its possessing any intensifying action, it behaved as a reducing agent, and this is certainly the capacity which, from actual experience, we should ourselves expect it to exhibit.

Some three years ago—in January, 1884—we published in these columns some notes on ferric and potassio-ferric sulphates, in the course of which we detailed our experimental attempts to utilise these two substances as negative reducers. Though our experiments were conducted with the potassium salt, the different iron alums are so similar in constitution, character, and properties, that we have little reason to suppose that the ammonia-iron alum will behave in materially different manner from its congener. The chief difference between the two will be found in the fact that the ammonia compound is slightly more stable than its fellow, a circumstance that may cause some of the phenomena we have to record to be less marked than with the potassium salt.

In describing these curious compounds, we may state first of all that the term "alum" applied to them is, strictly speaking, a misnomer, since they contain no trace of alumina, but receive the name because they are isomeric with the double sulphates of aluminium which pass under the generic title of alums. They are, in fact, double salts in which the sulphate of iron (ferricum) replaces the corresponding salt of aluminium. Thus, when ordinary potash alum without its water of crystallisation is represented by the formula $\text{Al K} (\text{SO}_4)_2$, potash-iron alum has the composition $\text{Fe K} (\text{SO}_4)_2$, and each contains the same proportion of water of crystallisation, namely, twelve equivalents.

The iron alums are made by mixing their component sulphates in equivalent proportions in the presence of a slight excess of sulphuric acid and allowing the double salt to crystallise spontaneously. The crystals have precisely the same form as the true alums and are colourless, or nearly so, commercial samples exhibiting generally a slight pinkish or brown tint. Potash-iron alum especially is peculiarly liable to decomposition, particularly when heated and in its solution, decomposes slowly at normal temperatures and very readily if heated to 180° Fahr., separating into insoluble basic potassio-ferric sulphate which is deposited, normal ferric sulphate and free sulphuric acid. If kept for some time, however, this solution yields, on evaporation, crystals of the original double salt.

Ferric sulphate, more popularly known amongst photographers as persulphate of iron, was first suggested as a reducing agent for negatives by Mr. Warnerke at an early meeting of the Photographic Club, on account of its solvent action upon metallic silver; but we do not recollect to have heard of any such application of it having been made in connection with gelatine plates until our own experiments in 1883 and 1884. If metallic silver be immersed in a cold, strong solution of the persulphate, it is slowly dissolved, and after a time redeposited as a fine metallic powder as the solution becomes gradually decomposed. If the solution be heated the silver is dissolved more rapidly, in fact with considerable energy; but the decomposition of the iron salt also takes place more rapidly, and consequently the reprecipitation of the silver as well mixed, in this case with a considerable quantity of the insoluble yellow basic sulphate. If the solution be acidified with sulphuric acid, however, the silver is thrown down in a state of great purity.

The double salt of potassium and iron, though less liable to change, is still subject to precisely similar decomposition to those mentioned, though they occur more gradually, and it was for this reason that we were led to try the potash-iron alum in the first instance. The ammonia compound being still more stable may, as we have already suggested, possess slight advantages over either, but we do not apprehend that they will be such as to render that salt of any practical value, for the reasons we shall give.

If we proceed to treat a fixed and well-washed gelatine negative with iron alum, we find that the image is rapidly removed by the solvent power of the solution. Removed, that is to say, so far as its original character is concerned, for though the silver is dissolved out, its place is taken by a deposit, more or less strong, of the insoluble basic iron salt already mentioned, which forms a faint, dirty yellow image. But in addition to this action on the image, the clear portions of the film become tinged of a deep yellow colour, the character of the stain varying with the strength of the solution. If the latter be weak, the stain remains transparent, but in proportion as the strength is augmented, so does the tendency to opacity increase, until with a very strong solution the faint image almost ceases to be discernible. If an unfixed negative be so treated the image disappears as completely as if bleached out with chloride of copper.

As the strength of the solution is decreased the solvent action upon the silver forming the image naturally becomes less, but to a greater proportionate degree than the staining power. Consequently, if a negative be immersed for a short time in such a solution, the shadows become stained before the

image is materially reduced in strength, though complete reduction will take place if a sufficient time be allowed.

These facts may possibly supply us with a clue to the claim made by the writer in the *Photographic Times* that ammonio-iron alum will at the same time clear away fog and intensify a negative, though it will depend upon the exact nature of the fog whether or not our theory is applicable. Fog in many, perhaps the majority, of cases consists of a surface deposit, as, for instance, when it is caused by slight access of white light in the developing room or by forced development. If it be chemical fog created in the emulsion it will necessarily exist throughout the whole thickness of the film, and then the theory we propose seems less probable.

Given a solution of the ammonio-ferric sulphate of such a strength as to act slowly upon the metallic image, we can readily conceive that it will exert its influence first upon the surface of the film, and if the fog be purely superficial that may be expected to disappear before the built-up metallic deposit is appreciably affected. Even granting that the fog deposit reaches throughout the whole thickness of the film, we are warranted in believing that it may be totally removed before the more solid portions of the real image are greatly affected; since, as the solution penetrates those parts of the film, its solvent power is exhausted by the surface metal, and by the time it reaches a certain depth into the gelatine it has become totally deprived of all power of acting on the silver. It is, then, only by the gradual exercise of the process of osmose that a sufficient quantity of active solution is brought to bear on the image portions of the film, while where only slight fog exists the solution is absorbed into the film with less drain upon its powers, and consequently may eliminate the fog before the image is materially affected.

With regard to the alleged increase of density we are disposed to think that this is, if not purely imaginary, based upon a fallacy, or rather upon the stain, imparted to the gelatine by the iron solution. We all know how greatly the density of a negative is apparently reduced by treatment with alum and citric or hydrochloric acid in order to remove the pyro stain. Inversely an appearance of greater density will follow the yellow stain given by the iron, but how far the apparent intensification is real can only be estimated by actual trial. Such dodges as printing through a coloured varnish or sheet of tissue-paper which supply a uniform increment of density to lights and shadows alike, are resorted to with advantage with very thin negatives, so, possibly, the application of an even stain to the film itself may have a similar result; but obviously the treatment must be of limited application.

One other explanation of the alleged intensifying action suggests itself as we conclude. Some years ago Mr. R. Kennett published a method of *slightly* increasing the density of a negative and at the same time clearing it, consisting in plunging the plate direct from the fixing bath into a solution of ferrous sulphate. Possibly there is something in Mr. A. L. Henderson's suggestion with regard to the presence of hypo in the film having something to do with the result, so far at least as the intensification is concerned. But in any case we fail to see how the staining difficulty is overcome.

THE OLD SYSTEM OF TONING.

A SHORT time back we directed attention to a series of photographs of scientific celebrities which are to be seen in the Patent Museum at South Kensington. These portraits were produced

long prior to the introduction of the system of toning with alkaline gold bath. Although a large proportion of those prints are, we believe, now upwards of thirty years old, yet many of them show very little, if any, signs of fading. Some, it is true, have become exceeding yellow, but where they have the change in most instances has not been accompanied by any very serious loss of detail. Taking them as a whole we very much question whether a similar number of prints, taken promiscuously out of a lot produced by the alkaline method only one-fourth the time these have been, would present any better, if so good, an appearance.

We have ample evidence that some of the earliest prints which were toned in the compound toning and fixing bath are still as good as when they were first taken out of the washing water, and, what is more, many of them did not receive anything like the care in the washing which is bestowed upon those of the present day, yet they do not appear to have suffered therefrom. It is manifest, therefore, that under some conditions pictures toned and fixed in the same bath may be permanent—that is permanent in the general acceptance of the term. We know also that some prints toned in the modern gold bath, and upon which every care has been bestowed in the fixing and washing operations, have shown unmistakable signs of fading after the lapse of a very brief period. This naturally leads one to ask, in face of these facts, if the present method of toning with alkaline gold is after all really the best, and whether, if the old plan were reverted to, a greater degree of permanence might not be secured?

Most who remember the method of using the compound toning and fixing bath are quite aware that sulphur must have played a very active part in the colouration of the prints, because it is well known by those who used it that the bath was usually employed—and it continued to tone—long after it must have become exhausted of its gold. With this knowledge before them many of the old school have been led to surmise that, with our improved knowledge, were we to go back to the former plan of toning and fixing in one operation the prints would prove more permanent than they do with the present system. It must be admitted that after nearly thirty years of trial the alkaline process of toning is found wanting, so far as stability of the results are concerned, yet, theoretically, it is far preferable to the old plan.

Here is another phase of the question. Suppose we were to go back to the compound bath, should we obtain the same rich tones as of yore? To this we unhesitatingly answer in the negative, unless at the same time we were to revert to the old kind of negative and the former system of heavily salting and strongly sensitising the paper upon which the prints are made.

Since the old toning and fixing bath was discarded photography has undergone a complete revolution as regards the character of negatives and the amount of silver contained in the paper, also in its albuminous coating. Originally the negatives were made exceedingly dense in the lights, while the shadows were kept scrupulously transparent, great density being at that period considered an essential to a good negative. Some of the old negatives took from half a day to a day to print in a moderately good light. The albumen was always highly charged with chloride and moreover was used diluted with water. The paper used to be floated for twice the time now given, whilst the silver bath was about double the strength of that at present employed. Furthermore, the picture was always printed considerably darker than is now customary, as it became reduced very much in the toning. Consequently

when the print was removed from the frame it was strongly bronzed in the shadows and the image was deeply in the body of the paper, sometimes showing strongly on the back.

When a print of this character is immersed in the compound toning and fixing bath the first change of colour is to that of a brick red—similar to the tint assumed when one is placed in the ordinary fixing bath before it is toned. From this brick red the colour gradually changes to brown, then to purple and on to black, and, finally, an inky black. If a print of the opposite character, such as those produced under existing conditions, be immersed in a compound toning and fixing bath, it would take a paler tint to begin with and could not be toned beyond an unsatisfactory yellowish brown colour.

Hence, if we were desirous of again adopting the system of toning and fixing in a single solution we should necessarily have to alter our present conditions of working entirely, because with the present character of negatives, and the lightly salted and correspondingly lightly sensitised paper now in use, it would be quite impossible to obtain the same rich tones as formerly.

HAVING reason to know that the group of the members of the Photographic Convention which we issued last year was greatly appreciated, it gives us pleasure to announce that a companion picture, printed in the same high style of collotypic art, will be given with our issue of next week. The negative from which it is printed was produced specially for us by Mr. John Stuart, of Glasgow; the scene is at Tarbert (Kyles of Bute), the occasion being one of the excursions indulged in by the members. The various likenesses are excellent and immediately recognisable.

PHOTOGRAPHS of lightning flashes, once looked upon as marvellous achievements, are now, comparatively speaking, common; but considerable interest yet attaches to them on account of conflicting theories still held as to the path and progress of the current of electricity from earth to cloud, and *vice versa*.

THE interest taken by photographers in all subjects connected with the production of the electric light "goes without saying." It is well known that some of the best known names in the electric world are equally celebrated in the annals of photography.

SOME of our readers who may be experimenting in the production of the light by batteries may read with advantage some remarks by M. Sambue, in the *Revue d'Hygiène*, on electricity in the house. He points out the important bearings it has upon hygiene, one of these being the liberation of hydrogen gas where strong batteries are used in which zinc is dissolved by sulphuric acid. Besides the danger of breaking the vessels, this gas, mingling with the surrounding air, may form an explosive mixture. Then, again, from the presence of foreign bodies, the gas may become dangerous in other ways—sulphur, arsenic, and phosphorus being no uncommon accompaniments of hydrogen made from common materials. As an example of this danger, it may be mentioned that a chemist is known to have lost his life through the inhalation of a small quantity of arseniuretted hydrogen.

From the dark room such batteries should be entirely excluded, the danger being very insidious in character. When Bunsen or Grove batteries are employed the fumes are more readily perceived by the olfactory organs, although, to our own knowledge, the precautions that it might be assumed would be, as a matter of course, taken by every one to avoid injury from their presence are not always taken. Our co-operation had been asked in the matter of a scientific *conversazione*, and we brought thereto a number of valuable instruments, some of which contained intricate brasswork, the main part of which was unlacquered. After having arranged our apparatus, in a comparatively small room, our readers can judge of our astonishment when another exhibitor calmly proceeded to fix up a six-cell Bunsen within a foot or two of our valued instrument. Insensible to our

remonstrances that in a closed room full of visitors the fumes would be injurious to them, he was only persuaded to remove his batteries into another room by our threat that we should at once remove our exhibits if they were exposed to such vapours. In a similar manner we may imagine such fumes might be disregarded in the dark room by an enthusiastic experimenter, with results that might possibly result in very grave danger to his health.

A RATHER singular effect of the use of electric light has lately been described by Professor Wiesner, of Vienna. It has been found that a large number of works in the Library of the Technical School had become very yellow, and this gentleman was asked to investigate the cause. He found it to be owing to the powerful rays of the electric beam, which had an action similar to that of the direct solar rays. The particular effect in question was caused only in papers in whose composition ligneous substances, such as wood, straw, jute, &c., entered. He further pointed out that in paper from which the lignine by some chemical means had been removed the yellowing effect did not take place.

THESE remarks have a very important bearing on the question of the so-called "permanency" of photographs, the difference between the fading or alteration of the image itself and the discolouration of the paper base upon which it rests being one not always kept in sight when this question is discussed. Professor Wiesner has explained the phenomenon to be one of oxidation, and evidently to some extent influenced by the amount of moisture present. He points out that solar light acts more energetically than dispersed daylight, which itself exerts but a very slight action, especially in a dry room. Gaslight is nearly harmless by reason of the few re-frangible rays it contains.

THIS latter explanation requires explaining. It is to be understood that the radiations only from the light are under consideration, and their results are to be looked upon quite apart from any question as to the possibility of harm in the products of combustion of gas burnt in the atmosphere of a room without provision for the removal. We unhesitatingly assert that the fading of a large proportion of existing photographs that have faded in the course of years is due to these gaseous products, or to others resembling, but whose presence in the air is to be traced to the combustion of coal. We hold a very strong opinion as to the baneful results upon photographs that these products of gas or coal combustion bring about.

THERE are few photographers who have not, at one time or another, experienced the annoyance of a picture spoiled by some careless hand having made an ink-stain upon the mount. Oxalic acid is usually employed to effect the removal of such an intruder, but we have lately read that a new ink remover has been devised, the inventor of which attaches so much value to it as to have patented the mode of manufacture. The formula runs:—To two quarts of water, which has been previously boiled and cooled, add four ounces of citric acid, and after the acid has dissolved add from six to eight ounces of a saturated solution of borax and twelve ounces of chlorinated lime. Put the whole into a well-stoppered bottle, and shake occasionally in the course of several hours; then allow to settle and decant the clear liquid.

ECHOES FROM THE SOCIETIES.

I COULD not help feeling glad when I read Mr. C. Truscott's article on *Some Photographic Heresies* that I am not a writer on the scientific side of photography, otherwise I must have blushed. I must say, however, that I think he is rather hard upon the class, possibly because he does not know them. "Many of our best photographic writers" are, he says, proverbially "but indifferent photographers." Now, I myself have had the good fortune for many years past to enjoy acquaintance with very "many of our best photographic writers," and my experience of them is that as a rule they are far better "photographers" than the majority of those who call themselves so, and prate about being "practical workers" without being able to string half a dozen lines of English together to help their poor "theoretical" brethren out of difficulties.

"Correct theory is, of course, very useful," as, *of course*, Mr. Truscott is compelled to acknowledge; but his insinuation or implication that "false theory," or "theory founded on imagination or superficial experiment," forms the bulk of the "very fine writing" of "our best photographic writers," is not only ungenerous and ungrateful, but shows a lack of observation on his own part.

But in his next paragraph we get an inkling of what Mr. Truscott considers or has considered "heresies;" heresies, in fact, from which he appears to have been tardily converted, and in this year of grace and jubilee proceeds to lecture his fellows upon. It seems that when "the journals were half full of the heresy of emulsion photography, . . . nobody but enthusiasts" (of whom he evidently did not reckon himself one) "would read such rot." *Ergo*, it was "heresy" not to believe what you did not read; but when Bennett *showed* what could be done, the photographic world, including Mr. Truscott, woke up. Is it fair, though, to blame photographic writers because photographic heretics are too lazy or too unconcerned to read, but prefer to wait until facts are rammed into them by force? Does Mr. Truscott consider it the characteristic of "the intelligent workman" to wait to have information supplied to him in much the same manner as nutriment to a Strasburg goose under the process of fattening?

"Another heresy of mine," he says, is that "development is not the simple matter some people would have us believe." Now this goes further still in fixing the nature of Mr. Truscott's "heresies," for from the very earliest days all "our best photographic writers" have been doing their utmost to instil into the minds of their readers the very same idea, and it is only heretics of Mr. Truscott's class who have gone on flattering themselves that they know all about development, or that it is a purely mechanical operation. That he has not even yet mastered alkaline development, "*little science*" though it may be, is very clearly proved by his attempt to draw an analogy between it and wet plate development.

Once more Mr. Truscott's remarks on the subject of rapid plates and lenses fall short of the point. The "beginner" who, because he has a rapid lens, must always use it at full aperture, and the steam-power user who must always work his boiler at the full pressure it will bear, are, to my mind at least, about as wise in their generation as the man who buys so-called "instantaneous" plates and persists in making drop shutter exposures when, say, copying oil paintings. I would willingly pay ten dollars a-week more to an intelligent workman than to one of these; yet Mr. Truscott considers it heresy to do otherwise than work at the highest of high pressure!

Seriously, while the Photographic Society of Philadelphia numbers in its ranks many practical photographers, both amateur and professional, including some who are well known writers, and one or two whom I have had the pleasure of meeting personally and whom I know to be above the rank of Mr. Truscott's "heretic," I am surprised that no one took up the cudgels on behalf of the representatives of the scientific side of photography. Practical experience is always valuable, but "rule of thumb" is not worth a dollar a-month anywhere. The scientific writer is generally in possession of, at least, some of the former quality, but he who ventures to run down theory can have little but rule of thumb to fall back upon.

In the discussion on the subject of quick *versus* slow plates the difficulty was mentioned of making short exposures by uncapping and capping the lens when very rapid plates are employed. It is surprising that no exposing shutter for outdoor work has yet been devised which, without being expensive, will give an exposure of a fraction of a second or several seconds at will. I say this with the full knowledge that there are numerous shutters in the market which afford facilities for "graduating" the exposure, some of them to give exposures of definite duration, but these are all complicated and expensive, and even if accurate in their timing do not meet the want.

The shutter I have in view should be on the principle of Cadett's for studio use, which enables an exposure of any length to be given, the lens being opened at the will of the operator, and closed instantly should the sitter move or a gust of wind come. There are many instances in the practice both of portrait and landscape photographers where the operator is desirous of giving as long an exposure as his subject will permit; one second or two seconds will suffice, but he would prefer to give three or four, or perhaps more, if the sitter or the foliage will remain still. In such cases the clockwork shutter,

set to give a definite exposure, is worse than useless; indeed, I never could make out what was the idea that moved the mind of the inventor in devising a shutter that placed the exposure of a plate entirely beyond the control of the operator. Mr. A. Cowan described a shutter some years ago which in principle would fulfil the want I speak of, but I forget the details of its construction. All I remember of it is that one pressure of the pneumatic ball caused it to open, and a second closed it instantaneously. The difficulty of instantly capping the lens when a sitter moves, or when foliage is moved by the wind, is what I should like to obviate.

The new American "Wale" lens, first heard of on this side through the praises of an English photographer, became the subject of discussion at a meeting of the London and Provincial Photographic Association. I question, however, if "Mr. Wale," if there be such a person (it may be the name of a town) will be quite satisfied with the only information that appeared to be forthcoming regarding it, namely, that it was supposed to be "made in Paris and sold in America." Not that it is any the worse for being made in Paris. I daresay a very great many lenses bearing better known names than "Wale" are "made in Paris" and sold and used elsewhere, and, what is more, give every satisfaction.

What is the cause of halation? It seems to me rather a new dictum to set it down to "over exposure," as Mr. Crowe did recently at a meeting of the Liverpool Amateur Photographic Association. Taking the side of glass in a glass *versus* paper discussion, Mr. Crowe enunciated the astounding opinion that the film or nature of the material had nothing to do with halation, and showed in proof of his view some negatives upon glass which were free from the defect. Now the fact that one of these was the representation of a "glass roof with iron supports," proves nothing, unless that Mr. Crowe is unconsciously misleading himself. Nothing is easier than to reproduce such a subject without halation and without backing the plate if a proper exposure be given; but the difficulty is to give the proper exposure to the glass roof and well lighted parts as well as to the darker portion of the picture. Either under or over exposure will do the mischief as well as improper development, to say nothing of reflection from the back of the plate and lateral dispersion of the light in the film itself with many other proven causes. To say, therefore, that halation is caused by over exposure savours of the ridiculous. All the same I am not one of those who believe that paper does away with halation, because there are many causes, one only of which is overcome by the use of the paper support.

Then Mr. Crowe's argument that the same amount of minute detail cannot be obtained in a paper negative as in a glass one, because he "did not believe" that some specimens he showed could "be matched on paper," requires more force to carry conviction to other minds.

It is curious to note that the alleged greater rapidity of paper over glass crops up again, but if, as I take it, the experience of the members of the Liverpool Association is derived from commercial papers, I wonder how they arrive at their comparison without trying the same emulsion spread upon glass. Mr. W. Brooks stated some time ago that the same collodion emulsion spread upon paper was several times more rapid than on glass, and *there* was something definite to go upon. If the greater rapidity be real I would suggest as one cause that the developer acts, in the case of paper, simultaneously upon both sides of the film, and so, for reasons I could give more fully, produces a better result.

MONITOR.

THE PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.

THE EXHIBITION DEPARTMENT.

WHILE George Mason & Co. were much the largest exhibitors of apparatus in the Convention Exhibition, yet were there some others who also made a good display. Passing over for the moment the apparatus sent from elsewhere, McGhie & Bolton, of Glasgow, showed a good collection of the goods either manufactured by themselves or sold by them. We availed ourselves of an invitation to see their place in West Nile-street, where, as an adjunct to studio life, we saw various systems of electric and pneumatic bells. An apartment in the

rear was fitted as a studio in which to try plates or apparatus, and immediately adjoining was a dark room. In this establishment we saw replicas of the Convention exhibits and in greater quantity, including cameras of various designs for studio and field, and a small one entitled "The Tourist's Companion;" roller and other dark slides; lenses by leading and other makers; shutters, dark-room lamps, backgrounds, accessories, and the numerous indescribable things which go towards making up the sundries which must be kept by the modern photographic stock house. A conspicuous object among their Convention exhibits was a dark-room developing sink on the model of that for which the Photographic Society of Great Britain awarded a medal last year to George Houghton & Son.

Among those manufactures which are peculiarly of Glasgow origin is the emulsion separating machine. Two of these were exhibited by Watson, Laidlaw, & Co., one of them being of small and compact dimensions, well adapted for the requirements of the amateur or emulsion maker on a small scale.

The Albion Albumenising Company, of Glasgow, contributed washing troughs, portable and studio cameras, and an ingenious camera stand with a compensating balance arrangement.

The means of printing automatically by the agency of his patented apparatus was shown by Mr. John Urie, Glasgow, who exhibited both the machine itself and numerous portraits which had been produced by it. It is the same apparatus by which the illustrations were produced for our ALMANAC for the current year.

THE MANCHESTER EXHIBITION.

IV.

THE members of the Manchester Club make a fine display at the Jubilee Exhibition. It is impossible to give anything like a complete account of these exhibits, but we can mention with commendation *Views of Haddon Hall*, by J. G. Jones; *An Old Mill in Thorpe*, by T. Sefton; *Near Oversley*, by James Ford; *Melrose Abbey*, interior and exterior, by J. T. Foster; *Miller's Dale*, and other places, by E. Openshaw.

While good in other respects, some prints from collodio-albumen negatives by John W. Leigh would have gained in brightness had they not been cemented to the covering glass.

In *Rudston Church*, by T. W. Steventon, the clouds are rather too pronounced, the tendency in such a case, as in too great a wealth of accessories in a portrait, being to distract the attention from the principal feature of the scene.

Hung too high for easy inspection are a series of five photographs by A. Brewer, whose other exhibits are more fortunately situated in this respect. A darker background would have improved his *Organ Grinder*.

A mixed lot of eight views by J. Witham, including *Sands, Ramsey*, contain good, rapid, clean work.

The Manchester Photographic Society is represented in great force, but we shall devote a special chapter to them.

CONTINENTAL PHOTOGRAPHY.

[Translations and Abridgments.]

MISCELLANEOUS ITEMS.

THE death of M. Piquée, of Troyes, is announced; he was a writer upon the connection between painting and photography. The Photographic Society of France has sent an address of condolence to his widow.

The new little Society of Amateur Photographic Excursionists is now in active operation at Paris; its excursion to the Argenteuil quarries has already been described in these pages; since then it has visited the woods of Saint Cloud, to make a special study of the photographing of sylvan scenery.

The Central Union of Decorative Arts will open an exhibition in the Palace of Industry, Champs Elysées, Paris, on August 1 next; it will remain open until November 25. A section of it is reserved for photography and industries connected therewith. The conditions under which objects may be placed on view have been printed, and are obtainable upon application.

Recently we published how M. Haack removed the stain from negatives which had yellowed after intensification with bichloride of mercury, by treating them with sulphide of ammonium. M. Davanne had previously published a better plan, namely, their treatment with sulphide of sodium, the evil smell of which is fainter. In any case the treatment should be effected in the open air.

A volume of specimens of the work of the *Stabilimento Artistico per le Applicazioni della Fotografia*, of Milan, has been published, and a copy presented to the French Photographic Society by M. Vitterio Turati. Portraits of Niépce de St. Victor and Poitevin have been presented to the same Society by M. Nadar.

The French Photographic Society will inaugurate a photographic exhibition in Paris next spring; it will be open but for two days. Similarly brief exhibitions have had great success in connection with other scientific subjects in Paris.

A memoir, not explicable in detail without the aid of diagrams, has been read before the French Photographic Society by M. A. Blazy, describing a remarkable way of exposing paper or other films in the camera. The films are cut to standard sizes, and stored in a kind of book; they can be exposed one by one, and after exposure are caught by a band at the bottom of the camera and rolled up therein by turning a handle. This seems to be a decided novelty in the way of invention.

The subject of photosculpture has been revived in France, and a paper about it has been read by M. Lazard before the French Photographic Society.

A paper by Mr. Herbert Starnes on the direct printing of transparencies, has been translated and published in the *Bulletin* of the Belgian Photographic Association, also in Liesegang's German periodical, the *Lanterna Magica*, also in the *Bulletin* of the Photographic Society of France.

Messrs. Gædicke and Miethe have published in Berlin a method of burning magnesium instantaneously, or rather in times varying from one-thirtieth to one-fiftieth of a second, and of preventing the escape of smoke. They mix chlorate of potash and sulphide of antimony with the magnesium, and ignite them when used. Of course it would be dangerous to life to attempt to grind the above substances together; they must be ground separately first and mixed afterwards. The British Government will not legalise the manufacture in this country of any explosive containing chlorate of potash.

The Amateur Photographic Club of Vienna has begun to issue a journal called *Photographische Rundschau*, or *Photographic Review*.

The *Revue Photographique* of Paris, edited by M. E. Letellier, says that Vogel and Obernetter succeeded in preparing orthochromatic plates, which at midday in the middle of winter gave them instantaneous views, when ordinary gelatine plates would give only silhouettes.

Mr. Birtles's method of intensifying gelatine negatives has been published in the *Photographische Rundschau* of Vienna, and in *L'Amateur Photographe* of Paris.

The *Revue Photographique* says that the method of drying a negative has much influence upon the intensity of the image. A negative dried near a fire is more vigorous than if it had been dried at an ordinary temperature. A negative may be intensified by being wetted and then dried quickly; several times in succession.

The *Revue Photographique* says that it is an old point of discussion whether daylight is less actinic when the wind is in the east.

INTENSIFYING NEGATIVES.

M. G. Cassebaum says that negatives can be evenly and vigorously intensified in the following way. First steep the plate in a faintly acid solution, then soak it in the following bath:—

Nitric acid	1 part.
Water	960 parts.
Chromic alum	48 "

Rinse the plate well, then treat it in the following way. Prepare

A.	
Gallic acid	120 parts.
Alcohol	480 "

B.	
Nitrate of silver	30 parts.
Water	480 "

Mix 30 parts of each of the above solutions, then add thereto 480 parts of water; cover the plate with the solution and leave it therein until the required density is obtained. Then wash.—*Bulletin de la Société Française de Photographie*.

EARLY PHOTOGRAPHS.

After the recent death of M. Bayard, one of the founders of photography, and General Secretary to the French Photographic Society,

his widow offered the Society any of Bayard's relics of early photographic art which it thought proper to accept. M. Davanne, accompanied by M. Dupuis, accordingly went to Nemours to make the selection, which included a series of prints produced in the month of May, 1839, four months before Daguerre made his processes known, and which were then exhibited in aid of the sufferers from the earthquake at Martinique; the prints were mentioned at the time in the official journal *Le Moniteur Universel*. The prints have not deteriorated much, although at the time no means were known of assuring their stability. They also selected some very large Daguerreotypes, and some gold prints on paper, presented to Bayard by the Duc de Luynes. These relics will be religiously preserved in the archives of the French Society which feels grateful to Madame Bayard for her valuable gifts.

WAXING PRINTS.

Dr. Eder gives a brilliant surface to prints upon albumenised paper by treating them with:—

White wax	100 parts.
Dammar varnish	4 „
Rectified essence of turpentine	100 „

To preserve the solution it is put into a well-dried bottle, and when it thickens by evaporation a little more rectified turpentine is added. —*Revue Photographique de la Société Française des Archives Photographiques, Historiques et Monumentales.*

REMOVING SILVER SPOTS FROM NEGATIVES.

The negative is soaked for five minutes in pure water, then in—

Iodide of potassium	1 part.
Distilled water	24 parts.

It is left in the above bath for about ten minutes. When the spots are old ones the plate may be left in the bath for half an hour. It is next placed in a bath of—

Cyanide of potassium	1 part.
Distilled water	16 parts.

It is then carefully rubbed with a little cotton wool until the place formerly occupied by the spot is uniform in appearance with the rest of the picture. When the spots are very old indeed, the solutions may be stronger, and the plate left in them for a longer time. —*Photographische Rundschau.*

PROOF NEGATIVES FOR PHOTO-LITHOGRAPHY.

The negative proof is intensified in the ordinary way by pyrogallol and nitrate of silver, then fixed and washed.

After washing it is placed alternately in a bath of bichromate of potash and permanganate of potash, until it takes on a strong yellow colouration; it is then washed and dried.

Ordinary negative varnish is then applied to it, but coloured with an alcoholic solution of aniline blue.

Consequently, the ground of the negative, under the influence of the light passing through it, takes a deep black colour, and the lines become blue.

A proof negative, so prepared, gives with certainty corresponding results in printing. —*Photographisches Archiv.*

ON PHOTOBROMIDE AND PHOTOIODIDE OF SILVER.

PHOTOBROMIDE OF SILVER.

This substance is formed for the most part by the same reactions as the corresponding chlorine salt. It is not, however, to be supposed that all reddish brown substances resulting from the action of reducing agents on silver bromide are the photosalt. By reduction Ag Br may yield a brownish coloured form of silver, which, mixed with unreduced Ag Br, may form a substance resembling the photosalt, but having none of its properties. The two are easily distinguished by the action of cold nitric acid, which, added to a brown mixture of Ag Br and Ag, quickly dissolves the silver, leaving Ag Br. On the photosalt it has no action.

A beautiful variety of photobromide is easily obtained by dissolving silver nitrate in ammonia and adding it to ferrous sulphate previously mixed with a solution of soda. Then K Br is added dissolved in dilute sulphuric acid, until the mixture has a strong acid reaction. Sometimes this method gives immediately a fine purple, sometimes a brown product. But in either case, after washing and cautiously heating with dilute nitric acid, a beautiful purple results. Much care is needed in the nitric acid treatment, or particles of yellow bromide will form. A specimen obtained in this way gave figures indicating 7.25 per cent. of subbromide. Each specimen, however, varies in composition, often very materially.

I subsequently found it desirable in some degree to vary the method, and to determine the best proportions in which the materials were used, to obtain a constant product. That which I prefer to use is as follows:—Six grammes of silver nitrate are to be dissolved in 200 centimetres cube of water and ammonia added until the precipitated oxide redissolves easily.

Twelve grammes of ferrous sulphate are dissolved in 200 c.c. of water, and the silver solution is poured into this. Then four grammes pure caustic soda dissolved in 50 c.c. of water are added, let stand a few minutes, then five grammes of K Br dissolved in a little water. Finally, dilute sulphuric acid until the whole has a strong acid reaction. This product, well washed, and then heated cautiously with nitric acid 1.36, diluted with five times its bulk of water, gives photobromide of a shade of royal purple, extremely beautiful. Notwithstanding its fine colour it proved to contain but little subbromide, not quite one per cent. (0.98 p.c.).

Various other methods may be employed. Silver bromide may be dissolved in ammonia, and be treated first with ferrous sulphate and then with dilute sulphuric acid. This method, which is very good with the chloride, is less available for the bromide because of the less solubility of the normal bromide in ammonia, so that, although the product is good, it is small in quantity.

Very good results are obtained by dissolving silver phosphate, nitrate, and probably almost any other salt of silver in ammonia, adding ferrous sulphate, and, after two or three minutes, hydrobromic acid.

Potash bromide and cupric sulphate may be made to act on metallic silver in fine powder, but the product is contaminated with much copper, difficult to get rid of.

When Ag Br is treated with sodium hypophosphite a brown or brownish purple form of photobromide is obtained, which seems to be more easily decomposed by nitric acid than most other forms of this substance.

Potash or soda, with oxidable organic substances, made to react on silver nitrate, and then treated with H Br, gives the photobromide. With soda and milk, sugar, or aldehyde, a rose-coloured or pink product is generally obtained.

Reactions.—In strong solution of potassic iodide it dissolves, and this solution by dilution lets fall pale yellow normal bromide. With a weaker solution it becomes somewhat lighter in colour. With acid ferric sulphate there is no action in the cold, but with a few minutes' boiling the photobromide is converted into bright coloured normal bromide. In sodium hyposulphite it dissolves, leaving a little black residue of silver. With ammonia the action at first seems slower than is the case of the corresponding chloride, and if the ammonia is poured over the photobromide in small quantity it may seem to be without effect. But the photobromide, shaken well up in a test-tube with a large excess of ammonia, is almost instantly blackened. Exposed to light, the red shades of photobromide darken with great rapidity. Placed alongside of the corresponding chloride the contrast is very striking; a strong image forms on the bromide long before anything appears on the chloride; nevertheless, if these two films are thrown into a developing solution, the chlorides, on which nothing could be seen, gives a vigorous positive development, while the bromide, which already showed a strong positive image, develops a negative one. The details of this reverse development have been already considered in another paper.

As respects the direct effect of light, unaided by development, the contrast between its action on the normal haloids and on the photosalts is very striking. If a rose-coloured photobromide and some normal bromide are exposed side by side the normal bromide (formed in presence of excess of alkaline bromide) darkens but very slowly, while the photobromide is quickly acted on. I have seen deep purple photobromide change to brown all over its surface with less than five minutes' exposure to diffuse light in the middle of a room, an amount of exposure which would scarcely have produced a visible effect on normal bromide formed in presence of excess of K Br.

When photobromide is exposed to the spectrum, it shows the same difference in sensitiveness and darkens more rapidly than photochloride. But it gives little indication of colour. When exposed under coloured glass, photobromide gave distinct indications of reproducing colours, but much less favourably than photochloride. Under green glass it became bluish, under blue greenish, under yellow glass it bleached, and under red glass the red of the photobromide remained unchanged.

PHOTOIODIDE OF SILVER.

The most characteristic colour of this substance seems to be a fine rich purple. It is obtained in much the same way as the corresponding chloride and bromide, with this limitation, that an excess of alkaline haloid must not be present, as the photoiodide is quickly destroyed by it. The iodine salt differs much more from the bromide than does the bromide from the chloride, and two striking distinctions are, its easy decomposition by its own alkaline salt, and its action with ammonia, as will appear beyond.

A very easy and satisfactory method of obtaining the photoiodide is the following: Silver is to be reduced from the nitrate or chloride, in fine powder in any convenient way; I have usually employed Levoll's method. To a solution of potash, iodine is to be added until the liquid becomes almost black. This iodine solution is to be diluted and poured over the silver by degrees, keeping the silver constantly agitated, until the whole mass becomes clear, bright purple. Any excess of silver present may be removed by boiling with dilute nitric acid, but this operation requires far more circumspection than in the case of the corresponding chlorine and bromine products. The acid (1.36 was used) must be diluted with twelve or fifteen times its bulk of water, and the boiling must be very short, otherwise the photoiodide is converted into normal yellow iodide.

Another method by which it may be obtained is to add ammonia to

silver nitrate in considerable excess and to pour this into solution of ferrous sulphate. Potassic iodide is dissolved in very dilute sulphuric acid and added till the mixture has a sharp acid reaction. It is necessary to observe that the K I added must be somewhat short of a proportion equivalent to that of the silver. Any excess of silver may be removed in the manner already explained. Different specimens of the purple product in this way obtained gave various amounts of Ag₂I from 0.61 per cent. to 4.63. The same remark made as to the meaning of these determinations in reference to the other haloids applies to this.

The method of roasting silver oxide until it is black, and acting on it with the hydrogen acid of the halogen, which works well in the case of the chloride, does not answer well for the iodide.

When silver iodide is boiled with solution of sodium hypophosphite, it gives a brown product, evidently indicating that reduction to some extent has taken place; the hypophosphite solution may or may not show traces of iodine. The colour of the silver iodide may show a very marked darkening, and yet the solution may give no trace of iodine by the most delicate reagents. This was very difficult to explain until I found that silver iodide has the property of taking up and retaining small portions of iodine, a reaction not very surprising in view of the tendency I have found in silver haloids to take up foreign substances of very various natures, and also of the facility with which iodine is taken up by alkaline iodides. This property in silver iodide was verified by shaking up portions of freshly precipitated and still moist Ag I with iodine solutions. Alcoholic solution of iodine diluted until it has a pale sherry wine colour is quickly decolourised by Ag I, and the same thing happens with a very dilute solution of iodine in KI, which in a few minutes becomes as colourless as water. This reaction I found particularly interesting, for it not only explained the action of hypophosphite in the case just mentioned, but also gave a clue to the cause of a phenomenon I observed more than twenty years ago, and which then and long afterwards seemed to me an unanswerable argument in favour of the physical nature of the latent image.

At the time referred to, I formed films of pure silver iodide entirely isolated from foreign matter, by reducing metallic silver on plates of ground-glass, iodising them with alcoholic solution of iodine, or with Lugol's solution, then washing most thoroughly under a tap for hours. When these films of silver iodide were exposed to light, they received an invisible image which could be developed. But these invisible images, if the plates were laid aside in the dark, had the property of fading out in a few days or weeks, then could no longer be developed, but the film could receive a fresh image. This seemed an unanswerable proof of the physical nature of the latent image at least on silver iodide. The argument was: If the production of this latent image is the result of chemical action involving the loss of iodine by the silver salt, how then is this iodine recovered when the image fades out? If it is formed of subiodide, where does this latter substance get back its iodine to return to the normal form, as it unquestionably does?

No answer could be given then or after, and this experiment, repeated and confirmed by others, has always seemed the strongest support of the physical theory. When, however, it appears that silver iodide can take up iodine and hold it, the course matters follow becomes evident. By the action of light a very small quantity of subiodide is formed, and combines with the normal to form photoiodide. The iodine set free evidently does not pass off, but remains combined with neighbouring molecules of Ag I, and in the dark gradually recombines with the photoiodide, reconverts it to normal Ag I. In this retention the lower tension of iodine, as compared with bromine and chlorine, no doubt plays its part.

In thus explaining away the fading out of the latent image on silver iodide, the last argument in favour of the physical theory is destroyed, while the chain of proof supporting this new explanation, that the latent image consists of normal haloid combined with its own subsalt, remains unbroken.

Reactions.—When ammonia is poured over purple photoiodide of silver the colour quickly passes to a salmon and then, even after some days, seems to undergo no further change. Of separation of metallic silver, as in the case of the corresponding chloride and bromide, there is no trace. In sodium hyposulphite it dissolves slowly, leaving a slight but distinct residue. Dilute nitric acid mixed with dilute solution of K I slowly but completely converts it to normal silver iodide. Light acts slowly upon it, changing the colour to greenish grey.

I have already spoken of the remarkable manner in which light acts reversely by development on photobromide. On photoiodide the effect is usually the same as on photochloride, namely, the action is direct; but occasionally it reverses, and the exposed part comes out lighter in development than the part that has not been exposed. In this respect the behaviour of the iodine compound is intermediate between that of the chlorine and the bromine.

NOTE IN CONCLUSION.

The investigations of which the preceding pages are the result are still unfinished. I have very lately observed the formation of another group of silver haloids quite different from the photosalts. The members of this new group are deeply coloured, purple or red, not unlike the photosalts, but are sharply distinguished from them by very different reactions. The photosalts are unaffected by cold, strong nitric acid; these new salts are by very dilute acid instantly converted into a pale pink substance

which appears to be a photosalt. But the most striking difference is in the action of ferric chloride. A strong solution of this substance shows no action with the photosalts unless left in contact for many hours or days. But these new haloids are instantly converted by it into what is apparently light pink photosalt. So energetic is this action that a solution of ferric chloride, containing one part only to a thousand of water, quickly attacks these dark purple salts and decolourises them. Such a solution might remain indefinitely in contact with the substances I have called photosalts without affecting them. Other differences exist. So far as I have yet been able to observe, these new haloids are formed pure, whereas the photosalts are almost always contaminated with either free silver or free subsalt, or both. As yet there has been no time to fix with exactness their mode of formation or their properties, which I hope to do at a future day.

M. CAREY LEA.

—*The American Journal of Science.*

PRINTING IN CARBON, AND OIL COLOURS, AND PHOTO-LITHOGRAPHY.*

Mr. Poncey's efforts were next directed to the perfecting of his process for obtaining lithographic prints from nature, having all the detail and half tone of silver prints; towards this end he attained a considerable degree of success, taking into account the difficulties to be overcome. But the opinion will probably gain ground that neither he nor any other man will ever produce perfect prints from nature by means of photo-lithography, and that no advance is to be looked for beyond the point Mr. Poncey has reached, unless an entirely new method of dealing with the stone is discovered. There are mechanical difficulties in the way which are practically insurmountable.

Subjects in black and white can be readily produced. I have here a photo-lithograph taken at haphazard from a number of a journal devoted to architecture. To produce this a photographic print was evidently taken in reduced size from the original large drawing, for the fineness of the work is such that it could not be drawn to the size and reproduced at the price; there is little more to be desired in the reproduction of line drawings than is shown here. The printing of pictures from nature is altogether a different matter. In a lithograph the appearance of half tone is produced by lines or by dots, closer or farther apart, thicker or thinner, but every line and every dot is of the same degree of blackness; this constitutes the difficulty. If the stone takes the ink at all it takes it as a dead black; if half tone is desired in the photo-lithograph from nature it must be represented as in the lithograph, by dots. To produce these a grain must be given to the stone finer or coarser according to the subject, or the effect of grain can be produced by printing through muslin or other material which will give it. Artistic prints from nature of architectural subjects with a considerable degree of half tone can be produced in this way, as you will see from this photo-lithograph of Tintern Abbey; but for landscapes with aerial effects in perspective the process is not so satisfactory, the tints are so broken up and print so irregularly, especially for the distance, that nothing approaching the appearance of the original photograph can be obtained, at least in small sizes.

I will hand you some photo-lithographs in illustration, and will go on to the latest and greatest discovery of Mr. Poncey. The process I am going to speak of is a secret one, and you will not therefore expect me to say much as to the working of it. The secret is known only to the inventor and to myself; how I became possessed of it I will relate presently.

Soon after Mr. Poncey had invented the carbon process, a means suggested itself to him of producing photographs in oil and mineral colours direct upon any material, without the intervention of any organic matter to unite the oil colour to its support; such prints he thought would be more durable than those in which gum and gelatine were used, as in all carbon and similar processes. Gelatine is an animal substance, and as such is subject to decay, and as it is an acknowledged law in mechanics that a chain is only so strong as its weakest link, so it is equally true that a print is only as durable as its weakest element. If an image is partially formed of, or is united to its support by, gelatine, it seems only reasonable to suppose that when the gelatine decays the image, though formed of a permanent colour, having lost the link which united it to the paper, must suffer.

Mr. Poncey had also the hope that he might succeed by means of this process in obtaining prints in lithographic ink for transfer to stone, having all the half tone and other characteristics of an ordinary photograph, and, succeeding in placing such a photograph on stone, some means might be devised of obtaining impressions equal to it. He has succeeded in placing upon the stone photographs in lithographic ink of the highest class of artistic excellence, but he has not succeeded in obtaining lithographs equal to them for the reasons stated before. Mr. Poncey was working hard at his new process in 1860, and before 1864 he had brought it to some degree of perfection.

I have a few words to say here on what may be termed the Due de Lynnes episode. In 1856 the Due de Lynnes offered a prize of 8000 francs, open to all the world, to be given to the artist who should in three years discover a process by which photographs could be produced having

* Concluded from page 475.

all the characteristics of a photograph combined with the permanence of a printed engraving; 2000 francs were to be given to the competitor who in two years made the most important advances in "working off." A Commission was appointed to examine the exhibits and to award the prize. Mr. Pouncy sent in prints for the competition, and a silver medal and 400 francs was awarded him by the Committee, who postponed their final decision to 1864. And now comes the curious part of the story. Before the end of 1864 Mr. Pouncy had discovered the means of producing prints in oil colour; he sent specimens to the Commission as a candidate for the prize, and offered to attend in person and produce prints in their presence so as to satisfy them that the process fulfilled all the conditions required; this they refused, and as there was no other candidate who approached the standard, the prize was still unawarded in 1864, and remained so till 1867. In the February of that year Mr. Pouncy read a paper before the Inventors' Institute, Trafalgar-square, London, *On Sun Painting in Oil Colour*. THE BRITISH JOURNAL OF PHOTOGRAPHY, in commenting on this paper, stated that it was "illustrated by some of the finest specimens of photography without salts of silver that had ever been submitted to public inspection." The *Times* also contains a very favourable notice, and both these papers are circulated in France. Mr. Pouncy also gave notice that his specimens would be in the Paris Exhibition the following month. This appears to have stimulated the Prize Commission to come to a decision, and they in the following month, before Mr. Pouncy's specimens could reach Paris, awarded the prize to M. Poitevin. What had M. Poitevin done to deserve this distinction? He took out a patent as early as 1856 for printing in pigments, but, as the Editor of the *Photographic Notes* stated, "His patent is so indefinite that one is inclined to believe that he patented an 'idea' rather than a process which he had already tried and found to answer." This is borne out by the fact that M. Poitevin did not exhibit a carbon print or a photo-lithograph before Mr. Pouncy published his process, though there was the strongest inducement to any one to do so—particularly to a Frenchman—in the offer of the Duc de Luyne's prize. It was Mr. Pouncy, and not M. Poitevin, who received the medal and 400 francs. Why was not the prize awarded to M. Poitevin in 1859? Why did he not receive it in 1864? Why was the prize unawarded in February, 1867, and given to M. Poitevin in the following month, when the highest praise was being given by the most influential journals to the specimens which Mr. Pouncy announced he would exhibit in that month in the Paris Exhibition? What more had M. Poitevin done in 1867 than in 1864? what new discoveries had he made in the interval? The answer is that he had made no new discoveries, but he was a Frenchman, and it is impossible to resist the conviction that had Mr. Pouncy been a Frenchman, the prize would have been awarded long before. When Mr. Pouncy first exhibited carbon prints and photo-lithographs he was without a rival, his prints were everywhere alone, for there was no one else who could produce them.

The stereograph I hold in my hand is marked on the back, "Pouncy's process, first attempt, Saturday, February 14, 1863." I was in those days admitted freely to Mr. Pouncy's studio, and the idea occurred to me that I would find out his process and surprise him with a print by it. It was more as a mental exercise and as a joke than for curiosity. I was not allowed to see any of the operations though I was allowed to visit his laboratory. I had studied chemistry a little. I could therefore at once divide all the chemicals in his possession into two classes—those which might, and those which could not, produce the results. This left me with very few chemicals; but the question was how to use them. To witness one operation would give me the secret of all the others, and one day Mr. Pouncy invited me to witness one operation. After a few days of hard work in experimenting, this print was the result, and it *did* surprise him.

I found it the other day; it had been lying covered with dust in a drawer for twelve years, and had previously been lying about with rubbish in an outhouse. It was covered so thickly with dust and dirt that the subject could not be seen until it had been washed. You will observe that though it is not so beautiful or so perfect a photograph as Mr. Pouncy's, for it is a first attempt, it has pure whites and half tones, and there is no fading anywhere. This is the only photograph I have produced by Pouncy's process, but the knowledge of the working of it has given me confidence in speaking of it, and has enabled me to estimate and appreciate its great value.

I have in this frame specimens of prints on paper and canvas photographed in oil colour; they were sent in October, 1868, to Mr. G. Dawson, the late talented Editor of THE BRITISH JOURNAL OF PHOTOGRAPHY, and at that time a lecturer at King's College, London, who undertook to test the prints and report upon them. You will observe he has entered upon each particulars of the tests he applied, and he has signed each entry. Hitherto very severe tests had been applied and had failed to injure the prints. Mr. Dawson applied tests of a different kind. Here, for instance, mounted so that you can compare it with the print from which it is cut, is a piece of the print which has been "steeped in cold water for six days, the temperature then raised to 200°, at which it remained for twelve hours." Here is another, "soaked in cold water for six days, then boiled for six consecutive hours," and a second part of the same, which was "hung up in an oven for six days, in a temperature varying from 200° to 400°; unchanged, if anything rather improved," is the concluding remark, and you can see for yourselves that it is so. I dare say, gentlemen, you have read *Alice in Wonderland* and *Alice in the Looking-glass*, and will

remember how the grinning Cheshire cat sitting on the branch of a tree gradually disappeared until nothing but the grin remained, which also vanished after a time, because there was no Cheshire cat left for it to exhibit itself upon; if so, it will help you to understand the behaviour of one of Mr. Pouncy's prints under the action of still more energetic agents than those I have mentioned, by means of which agents the operator succeeded in dissolving the paper of the print, leaving floating on the surface of the liquid the picture, which only broke up through lack of a support upon which to exhibit itself.

Having succeeded in producing pictures in one tint of oil colour, Mr. Pouncy next applied himself to the production of oil prints in any colour; in this he was also successful. The oil prints I showed you just now were of a greyish black tint; this portrait of Miss Kate Terry on panel is of a decidedly brown tint.

From the production of prints in any one colour to the reproduction of paintings in the colours of the originals, and of portraits and landscapes in oil colour, was a natural sequence. The experiments made by Mr. Pouncy towards this end have been eminently successful, and have resulted in the discovery of the most perfect process for the reproduction of paintings that the artist could desire. I shall have the pleasure of showing you the most beautiful, and, as I think, the most perfect *facsimiles* of paintings ever seen wrought by this process. This picture, printed direct on canvas, is a copy of a little painting. The subject—two or three donkeys with the donkey girl on the seashore, with a little bit of hazy sea and cliffs in the distance—is a pretty little bit of composition, but it is not, I think, by any artist of standing. It is chiefly of interest as being the first painting ever printed by the process and as showing to what perfection it was brought from the first. The large painting here is a copy of George Morland's *Gipsy Camp*; it is said to be his masterpiece. Notice how exact a copy it is; even the brush marks are reproduced, and the impasting is on the copy as in the original. On this sheet of iron is an untouched copy of the same which has been enamelled on to the metal. The metal looks like zinc, but is iron. Zinc would not have stood the heat to which this has been subjected in the process of enamelling. The painting of the *Lambing Season* is an exact transcript of the original by Sidney Cooper. It was purchased for £300, and was borrowed by Mr. Pouncy, who told the owner that he would make three copies of it, and the owner might then come and select his own. "That will be easy enough," he said; "I shall know my painting among five hundred." "Then you will be the most severe critic we could have," was the reply. The owner came at the appointed time and found four *Lambing Seasons* in a row. He walked up and down the line and said, "Is my picture here?" "It is, sir," said an attendant, "for I hung it up myself." The owner lighted a cigar and walked up and down the line several times and said, "The glass over the paintings is a little confusing." "Your picture had glass over it, and I was obliged to glaze the others also, or you would have recognised your own from being different to the others." The owner again scrutinised the pictures for some little time, and then putting his finger upon his own painting he said, not "This is the one" but "Is this the one?"

The original of the *Wappen Schaw* before you was painted by John Faed, R.S.A., and was purchased by James Baird, Esq., for one thousand pounds. The painter, writing to Mr. Pouncy of this copy, said it was "as good a transcript of my original as can be produced. After mature and careful consideration of the principles and results of your invention I conclude that your *facsimiles* are the most perfect reproductions hitherto seen, therefore I shall have much pleasure in inspecting and signing the copies of my original." Accordingly you will observe that the copy is signed J. Faed.

You are competent, gentlemen, to form an opinion as to the artistic qualities of the paintings I have shown you, if you were not, you would probably accept the *Art Journal* as an independent and competent authority and critic. The *Art Journal* commenting on these pictures, said:—

"No one who has not seen specimens of paintings reproduced by the process in question can have any adequate idea of the wondrous fidelity of the copy to the original. No human copyist, of whatever skill possessed, could produce a work of such unerring accuracy, and such perfect fidelity of form and colour, light and shade, without variation of tint or tone, or subtle effect of the original painter's skill. The manner of the pigment observed in the original is found in the copy. The chromo-lithograph, the oleograph, marvellous as they are as mechanical productions, present only a general imitation of the picture copied; the common eye knows them to be copies, since they are entirely wanting in individuality and force, while the *facsimiles* by this process are exactly what the term implies. They are not merely *facsimiles* of general effects, they are *facsimiles* of actual effect, and of every effect, even more completely than if the copy had been born of the original picture. For purposes of pleasure, or education, or connoisseurship they are complete. A small gallery of such pictures would be as adequate for the promotion of taste, or the education in the characteristics of the masters, as a gallery of the originals would be. The invention appears to be one of the most marvellous additions to imitative art ever made known."

But we have by no means exhausted the purposes to which this ingenious invention can be applied. Having successfully overcome all the difficulties in the way of presenting, by means of photography, exact *facsimiles* of paintings, and of natural objects in every tint of colour, Mr. Pouncy turned his attention to ceramic and jannepers' colours, with which also, after many experiments, he was completely successful. Here

is a portrait burnt in on porcelain, another on *papier mache*, which has been stoved and varnished in the usual way. That large painting enamelled on to metal and fired, I have already shown you.

These paintings on panel, you will observe, have the appearance of having been painted in the richest sepia; the grain of the wood to which they are firmly attached shows up well in blank parts. They are so embedded into the very substance of the wood, that they can only be removed by planing off its surface.

In fact, there seems no end to the artistic application of this beautiful process. You will, doubtless, ask me how much artistic finish has been applied to the pictures I have shown you? It is a reasonable question, and I reply, To many of the pictures, none; to others so much, and of a similar kind, as would be applied to a carbon enlargement on opal or paper.

I will not detain you much longer, gentlemen. I have given you some account of the invention of carbon printing and photo-lithography. I have shown you specimens of work done by Mr. Pouney's process of photographic printing in oil colours. I will only remind you once more of the great natural uses to which this invention might be applied.

By adopting it the South Kensington Art Department need no longer send out to the schools of art in connection with them the inferior paintings of inferior painters, since they can, at a much less expense, place as models before their pupils all over the country exact copies of the finest works of the painters' art in the kingdom so true to the originals that the painters themselves could not have made such exact replicas. Towns, for a very small sum, might possess galleries of the works of the great painters, and thus hasten the education of the nation in art.

And to what domestic uses might it not be applied! Our old mansions might be more richly adorned, the panels of panelled rooms, as well as the walls of the picture gallery, might bear scenes connected with the lives of the owners from photographs taken at the time. The festivities on the coming of age of the son, with portraits of all associated with them, might thus be handed down to posterity; the marriage of the daughter, hunting scenes, favourite animals, noteworthy events, might all be portrayed, the whole furnishing an imperishable pictorial record of the history of the life of each succeeding owner, containing exact portraits of each member of the family and household. Then, again, the porcelain, the metal work, all might be enriched by it. Indeed, the domestic uses to which the invention can be applied are innumerable.

W. MILES BARNES.

WHERE TO GO WITH THE CAMERA.

HASTINGS.

ABOUT this time of the year you begin by asking yourself, "Where shall I spend my holidays?" in your own mind already determined it shall be the spot of the picturesque. Your wife blandly refuses to leave her home, which she thinks far preferable to being "left on the beach neglected, while you slave yourself with the camera, dashing all over the country. Up with the sun to secure such and such a *delightful effect*. Late hours at night developing trial plates. No morning promenade! No evening concerts! I much prefer to stay at home," &c. All this sort of thing you easily settle by a faithful promise to take only half the usual quantity of plates. Contentment reigns once more. Hastings shall be selected, a very get-at-able spot, with charming inland country. Passing over the ordeal of packing huge cases and portmanteaus, at the finish to find only a very small proportion of room for the pet apparatus. In goes camera, lens, and slides, jolly. Now where goes lamp, developing trays, and solutions? No room. Happy thought, the leather bonnet-box; bonnets must go some other way, anywhere for them. Beautiful. All's well until it is found out, then comes a rapid eviction, and the trays, lamp, &c., are once more without home or habitation. No help but pack separate, vowing how nice it would be to find for the nonce at the other end a ready-made dark room with chemicals awaiting you.

Should you occupy new diggings and intend developing plates, fail not to acquaint your landlord or lady of your particular hobby horse. It will explain away a lot of your after seemingly peculiar habits. Provide sheets of oilcloth to cover tables and prevent indelible pyro stains, and a bad name equally as permanent.

A run of two hours and you are high and dry at Hastings, surrounded with such an amount of camera work you are bothered where to commence.

On windy days, making foliage impossible, make way towards the old Castle, which produces a charming picture, the ruin being a most picturesque one. After paying your admission money, and by way of policy go through the form of asking permission to photograph, when you will be requested to give your pledge not to in any way damage the grass. Several fine views are to be had from the grounds. The Castle is Father Antiquity itself, standing at the extreme edge of a tremendous high cliff. Tradition kindly informs us it was built by the Romans and later on repaired by William the Conqueror. Evidently the merry old Romans had a great weakness for security and built the outer walls eight feet in thickness. A favourable light for taking the old chapel occurs about midday. Very grand also are the coast views looking towards Eastbourne on the one hand and delightful hilly country on the other.

A tramp to Ecclesbourne Glen well repays the exertion of climbing a mountain, namely East Hill, nicknamed by the local working cobbler on

the door of his hut "Mount Zion." Arriving at the top was tempted to blow off one plate, hoping to secure a lasting remembrance, if only a slight one, of the old town buried in the hollow, snug and well sheltered by cliffs and hills. Passing along by the coastguard's station a magnificent seascape presents itself, now specked with innumerable yachts and pleasure boats gliding softly by. Remarkable at this distance how distinct can be heard the splashing of the waves mingled with merry voices of happy folk giving vent to song. The Glen with its rustic bridge—although nothing so rustic or effective as its predecessor—is nevertheless a composing portion, forming a very pleasing bit. Photography, alas! with its limited gradation, cannot do justice to the delightful foliage surrounding, and gives but an idea only in skeleton outline. Palette only can reproduce the enchanting spot. To those it may concern let me say the light here is most deceptive, causing me to much under expose both plates. Do not mind giving a long time. Rather more than a mile further on you reach Fairlight Glen and the renowned Lover's Seat. Alp climbing to reach, I found here an old fellow performing small miracles, namely, carving ivory toothpicks and paper knives from pieces of bone, enhancing their intrinsic value by inserting a microscopic photograph. For one day this trip is enough; a shilling can be well spent with riding home by road.

A short distance from the town is Battle Abbey, standing well and making a noble picture, this most historic pile commemorating the battle with invading Normans, and marks the spot where Harold fell in the year 1066. The gateway remains in good preservation, and easily done, which cannot be said for pictures within the gateway, it being almost impossible to receive permission for this purpose. Leaving the camera outside it well repays a visit, if only to hear the very risky, risky story told *en route* by the guide and to note how clever the generals the finish, that you must pass individually through a narrow door, at which he poses himself all smiles awaiting your generous and kind gratuity. Two and a half miles across a pretty country, passing by an avenue of trees with distant rustic gate (a good return for one plate), you reach Normanhurst, the seat of Lord Brassey. Each Tuesday during the summer season the house is open to the public, an opportunity every visitor should embrace. Special attention may be given the library, containing the collection of curiosities made by Lady Brassey on her famous voyage in the yacht "Sunbeam." Also notice the handsome box acting duty for a letter basket, covered with pictures made by the lady herself. Visit the room containing old and rare china, mounted birds, moths, and butterflies of every conceivable plumage and nationality, and the sumptuous yellow satin wall hangings of Chinese manufacture. Permission should be obtained to photograph the grounds. The Lodge cottage is pretty and easily done from the road.

At least two or three days only would suffice to make characteristic studies among the queer old huts, boats, &c., at Old Hastings proper. Here you may always find natural and ready-made groups of men and boys unloading fishing boats, mending and making nets, and otherwise employed or unemployed as the case may be, but forming pleasing lines dear to the artist. Pictures jump upon you, as it were, full ready for "snatching." In their everyday attire fishermen are very good pictures, but very shy ones indeed. A faintest glimpse of a camera approaching will put them to flight. Should they not compose just to your wishes—wait, do not disturb, as any amount of coaxing will not retain them. I made this early mistake, and as a last chance promised to stand a large mug of beer to no purpose. A long, lean youth, who considered the trousers pockets the only and correct place for his hands, sowed seeds of discontent among them by remarking the offer was "too good!"

The lifeboat house with distant cliffs forms a good result. The beach again, roaming among groups of children fully equipped with spade and pails for seaside merriment, make always pleasing pictures, and at times useful foregrounds. Again, the "Peerless Pier" deserves a little consideration.

Making it a rule to work only under favourable conditions, was wind and weather bound for two or three days. Found the beach pleasantly entertaining. At times highly amused to watch and catch rapid glances of two cameras and three young gentlemen hopping and darting about in a manner most lively, with apparently no fixed idea what to do, but fully determined "to do" anything and everything. Instantaneous shutters are at times necessary evils, but its purpose is far fetched, I think, when its manipulator occupies a prominent position on the Parade, congregating a crowd of nervous spectators watching his fierce expression and marble attitude, awaiting a special wave, or favourable chiaroscuro. I trust I am an enthusiast! For an exposure have risked my precious (?) life on the extreme of many hundred feet above the sea level; to reach a much-wished sandbank, seen ungracefully carried thither by a broad-shouldered fisherman; under pretence of bathing engaged a machine, and when nicely out to sea opened reverse door and fired away to my heart's content—and surprise of the proprietor! But I do draw the line at stopping a public thoroughfare.

One and a quarter miles from St. Leonards, a pleasant country, you have Hollington Church, situated in the midst of a wood; a quaint structure, with corresponding graveyard. This church is much patronised by the sketeling fraternity.

Once again to Hastings, you are within reasonable distance of antique Rye, with its queer old Landgate Tower and quaintest of churches; Pevensey, where William landed his sixty thousand, brave and strong, Castle said to be the "most perfect of the castellated Roman remains;" Hurstmonceux Castle, again, is very picturesque; also Camber Castle and

the old Grey Friars. I mention a few castles knowing how dear they are to many amateurs. To those not this way content, can always find their wants met in delightful and healthy Sussex.

T. COAN.

A VOYAGE TO THE MOON.

[A Communication to the Photographic Section of the American Institute.]

The moon has been conceded an object of interest in all time and by all people. We find it is mentioned in the most ancient writings of the ecclesiastical and the profane. The rude and the barbarian have looked upon it with awe and wonder. The civilised and enlightened have studied its ever-changing phases with deeper interest than any other visible non-terrestrial object. Very many mothers have taught their children that the man whose image they pointed out on its surface was an object of terror, whose bundle of sticks often came to the backs of disobedient youth. The savage and uncivilised have counted their seasons and the length of their lives by its lunations. Lovers in many climes have whispered their joys and pledged their fealty by its reflected light, and counted the first circle of its changes after their union as the honeyed period of human existence.

To the astronomer the moon has ever been an object of primary interest. It has been the first object to fix his attention when his newly adjusted telescope is used for actual observation. He may try its penetrating power upon some star group in the distance of unfathomable space, or seek a test for its definition upon the satellites of some great planet, or the separation of a star from its companion, but his first enthusiastic study is almost sure to be the surface of that luminary which has all his days been an unanswered question. The student of nature is not content with the opinions of others when equipped with a first-class telescope; he wants the personal "I see" upon which to base his opinions regarding a subject upon which so many conflicting arguments have been advanced. He has learned that the moon's distance from the earth has been accurately measured, that its mass has been calculated, and its density determined. These are facts which have been mathematically demonstrated. He has been taught that "figures do not lie," but he is often a little sceptical regarding the truthfulness of all the theories of those who have made the figures. He wants to go over the ground himself; and that there really is ground for him to go over is the one fact for the demonstration of which some proof is now offered. When contemplating a long journey, we usually study certain conditions which it is expected may be met with. But in our present case, of whom shall we inquire? By one careful observer we are told that the temperature of the whole country we seek is far above any place on the earth; in fact that millions of years of unclouded sunshine, where the days are 351½ hours long, has changed the whole surface to a field of glass; that all water and air have been burned out of existence. Another tells us that the surface is a vast field of ice, and that there is plenty of the rarest kind of air. That, instead of crawling along, as we do here on the earth, pressed down by a load of fifteen pounds to every square inch of our superficial measurement, we would there be so cheered and buoyed up by our surroundings, that the heaviest person in our party would weigh less than thirty pounds. Competent engineers tell us, after careful measurement, they find that our journey would be one of more than 238,000 miles, a distance for the travelling of which a fast express train requires about three hundred days.

One of our party suggested that we should go early in the evening, as the moon must then be much nearer than when far up in the zenith. But that is a mistake. When the moon is just above our horizon the length of our journey would be about 4000 miles greater than when she appears highest in the heavens. The moon looks nearer when on our horizon, because we compare it with terrestrial objects in the field of vision. To dispel the illusion, look at the rising moon through a tube which will shut other objects from the view. A newspaper or large sheet of wrapping paper, rolled to a diameter of one or two inches, will serve for the experiment. Apparent size is often far from the actual. As an illustration of this, most of us would say that the moon looks as large as the sun. But in reality it contains only $\frac{1}{1600000}$ part as such matter; this apparent similarity of size resulting from the sun being four hundred times further from us.

One of the most curious and interesting relations of the earth and moon is found in the rotation of the moon around its own axis in the exact time required to swing in its orbit around the earth; consequently the same side is always towards the earth. And if the moon had no libration, we would never see more than one hemisphere of its surface; but as the moon has a swinging motion, similar to that of a slowly rotating top, some little distance beyond her north and south poles becomes visible. If the moon is inhabited, what a field there is for the enterprise of some lunar Cook, or other energetic excursion organizer, who would liberally advertise trips to see the earth. The length of the journey from the centre of the opposite side of the moon would be less than the distance between New York and San Francisco. He would very truly call the show a big one, and those who purchased his tickets would — when they came in sight of this world of ours — see an object more than fourteen times larger than any they had ever before looked upon.

A lunarian's walk by full earth-light must be a very brilliant affair in a light such as we would get from fourteen full moons. But time is pass-

ing, and each one must make his or her own calculations regarding the inhabitants of our satellite.

At the north-west corner of Second-avenue and Eleventh-street in this city stands a large, plain, well-built brick dwelling, which has during many years been the city home of a man known and esteemed among the great minds of his age as a leader whom it is safe to follow; a man the best years of whose life, and a large part of whose ample fortune, have been devoted to the advancement of astronomical science. To the older members of the section it will doubtless seem quite appropriate that we are thus reminded of the first President under whom our meetings were held, Lewis M. Rutherford.

To Mr. Rutherford is due the credit of organizing the plan by means of which the trip to the moon, partially described to-night, was made possible. Upon an ample lawn in the rear of the house before alluded to was erected, in the year 1866, one of the best private astronomical observatories of the time. The building is of brick, and in the main consists of a circular observing room, twenty feet in internal diameter, with a projection on the westerly side for transit and computing rooms. The twenty-foot dome of the observing room rests upon twelve wheels equally spaced in the iron coping of the brick wall. The lower edge or base of the dome is fitted with a band of cogs, which gear into a chain-belted wheel, actuated by a crank in the wall of the observing room. So admirably is this mechanism constructed, that the strength of a child is sufficient for setting it in motion. On two opposite sides of the dome, from base to apex, are openings, two feet in width, which are closed by shutters easily worked from below, and so devised as to screen the room from wind when open. In the centre of the room, resting upon a firm foundation, deeply imbedded in the fine sand underlaying the whole building and grounds, stands the telescope pier, a broad, high block of stone, and around this, but not in contact with it, is laid the floor. In the transit room, 189 feet north-west of Second-avenue, and 76.3 feet north-east of Eleventh-street, the transit pier was erected.

The principal instrumental furnishings of the establishment consist of a first-class equatorially mounted telescope of 13 inches aperture and 14 feet focal length; the readings of position are upon 18 and 20-inch silver circles. The driving power is a Remontoir escapement clock of the highest merit. So accurate is its movements that the photographic image of faint stars, requiring long exposure, have a wonderful sharpness of outline.

The photographing of celestial bodies, attempted at various observatories previous to 1863, left much to be desired in definition. From some experiments made by Mr. Rutherford about that time, in connection with a Government expedition, he was led to believe that a lens could be so constructed as to greatly improve astronomical photography, and, by a purely scientific method, he began his work of solving the problem. By the use of the spectroscope he found that a lens of crown glass, so constructed as to shorten the focus of the observing telescope about $\frac{1}{16}$, gave promise of good results. Through the use of specially devised mechanism and methods of trial—the description of which would require too much time—he constructed with his own hands such a lens. Only those who have attempted to grind, polish, and correct a thirteen-inch lens can well understand the labour involved in such an undertaking. When, on the night of March 6, 1865, this newly devised method was proven to be correct, by the production of the first really good photograph of the moon, it was at once expected that photography would occupy an important position in science, and add greatly to the advance of astronomical observation. That such expectation has been and is now being realised, no one questions. Within the next few days will be held in Paris a congress of astronomers for the express purpose of apportioning the labour of making a photographic map of the entire heavens, and it is expected to complete the work within ten years, and that these plates will show a vast number of stars which no human eye has as yet seen, even with the aid of the most powerful instruments. Certainly, we may be pardoned for expressing a little pride in the fact that all this was begun more than twenty years ago by a citizen of New York and a member of our section of the American Institute. From his observatory we started for the moon, or rather, under its great revolving dome, found means for pulling the moon down, to be hung on the wall for our inspection.

Our party consisted of three persons, whom we will designate as Numbers One, Two, and Three. At 10.30 p.m. Number Two entered one of the computing rooms across the lawn and called "time," by reporting the zenith clear and the air still favourable for first-class work, a coincidence averaging about twice a-year in New York City. Upon this announcement Numbers One and Three bundle up in heavy clothing, as though about to visit the North Pole. They know the weather is crisp and cold where the next few hours are to be passed.

As they enter the door leading to the dome, under which stands the great equatorial, the silence is broken only by the escapement wheel of the tall sidereal clock standing against the western wall, as its heavy pendulum swings to and fro with an accuracy most wonderful. No other sound. Not a word is spoken; each knows his assigned duty, and to it he gives his undivided attention. All feel that such time is beyond value, and must be utilised to the fullest extent.

Number One has charge of the telescope. The dome is revolved into position, and a long, narrow section, from base to apex, swung open, leaving a strip of clear sky visible, in the centre of which the moon

glitens like a disc of burnished silver. The great instrument is swung into approximate position; the driving clock, constructed to run one hour, is wound; and while Number One is busy making his final adjustments, we will watch Number Two, who has charge of the photographic department of the expedition. He has lifted a trapdoor in the floor near the stoue pier, passed down a short ladder, and entered what may well be called a troglodyte's laboratory, lighted by one small wax candle, as care is necessary to keep the temperature low. After a few minutes the pupils of his eyes are expanded sufficiently to permit seeing the bottles, baths, and dishes required for his work. But we have no time to describe his chemicals or his method of using them.

Meanwhile Number Three, the timekeeper, has adjusted the chronograph (in whose record there will be no personal equation), placed his small, dim lights where they will illuminate the clock and the room just enough to see what is going on, and then take his position, where he can hear distinctly the beat of the long pendulum, as its lower end, terminating in a hair-like wire, swings at each vibration through a glistening drop of mercury, closing the battery current uniting chronograph, clock, and shutter-adjustment on the telescope. All is now ready for action. Upon a signal being given by Number One, a sensitised plate is handed up from the cave, placed in its receptacle at the ocular end of the great instrument, just as it would be put into an ordinary camera. The touch of an electric button, and away we go, or rather, we all keep very still.

The great clock says one, two, three, and the plate holder is opened to the light of the full moon, whose image the great glass eye, fourteen feet away, has condensed to a circle of one and three-tenths of an inch. The buzz of the chronograph wheels is just audible as it records the time in hundredths of a second. The heavy pendulum has beat one, and the long focussed eye is closed, the plate-holder is returned to the troglodyte, who reaches from below to receive it, as he hands another up. And so the work goes on until early morning, when the weary and thoroughly chilled party seek rest in a comfortable temperature and among surroundings which their animal natures deem far more enjoyable.

One of the old Hindoo systems of theology taught that the souls of men could leave their bodies for short periods of time in quest of knowledge, where no human body could ever go, and upon their return, by imparting to their fellow men the wisdom thus gained, an endless existence of perfect happiness was secured. Thus wise must have been our trip to the moon. The mind or soul reached out with a question. Was it answered? Let us see if any knowledge gained can be imparted to others.

[Then followed the lantern exhibition of many slides, shadowing the moon's surface; its mountains, more than twenty thousand feet high; its craters, fifteen and eighteen thousand feet deep, and from one to three hundred miles in diameter, were graphically described, and an explanation of the various theories advanced regarding the existence of air and water on the moon's surface; and some of the arguments used in support of such theories were examined. Dr. Mason closed his paper and description of the work done at the observatory by expressing regret that the telescope had been recently placed in the observatory of Columbia College, where he feared vibration would prevent its use for fine photographic work.]

O. G. MASON.

THE ART OF MAKING PHOTOGRAVURES.

[A Communication to the Photographic Section of the American Institute.]

BETWEEN the years 1790 and 1802, Wedgwood and Davy attempted to utilise for artistic purposes the sensitiveness of the salts of silver to the action of light.

In 1839, Mungo Ponton, of Bristol, in England, announced the action of light on organic matters, such as gelatine, in presence of a bichromate.

In the fifteenth century may be placed the discovery of copperplate printing.

These three germs underlie the three essential elements of our process of photogravure, in which I am to endeavour to interest you to-night.

The first germ—that of the sensitiveness of the silver salts to light—is the germ from which has sprung the photographic negative. The second discovery—that of the action of light on organic matter in presence of a bichromate—is the germ of the photographically engraved, or photogravure, plate. The third gives the starting point of plate or intaglio printing.

I propose to trace briefly the growth of these elements to the condition in which you see them to-night.

The efforts of Wedgwood and Davy, who about 1800 projected on to a sheet of white paper, or leather, saturated with nitrate of silver, the shadow of the figure to be copied, the sun's rays darkening all but the shadow, were followed by the process of Niepce in 1814, who for the first time employed a camera, using bitumen or asphalt as the sensitive medium, and giving an exposure of some hours; then by the process of Daguerre in 1839, where the development of the latent image first occurs, thus reducing the exposures from hours to minutes.

Later, by the discovery of Herschel, in 1821, of the value of the hyposulphites for fixing purposes, a very important step; next, by the production of negatives from which positives could be printed, by Fox Talbot, in 1839; and, lastly, by the introduction of collodion, by Scott Archer, in 1851. It was this latter discovery that gave such an impetus to photography, so that it sprung at once into life as the new handmaid of art. For the next twenty or twenty-five years the history of the collodion process was the history of photography. But the undisputed reign of collodion finally came to an end, and for the last ten years the history of photography has been the history of the gelatine process. Gelatine, indeed, has been the vehicle by which photography has been carried into well-nigh every home and well-nigh every business. Yet, I think, many of us older hands look back with longing eyes, in spite of the many advantages of gelatine, to the crisp snap of the collodion negative, which gelatine has not been yet harnessed to give.

If I may venture the prediction, I think the history of photography for the next decade will be the history of orthochromatic work. Surely, next to the production of the colours themselves, there is nothing to be desired so much as the rendering of the true values of these colours. I place the orthochromatic or isochromatic negative as the highest point yet attained in negative making, and as constituting the outcome to-day of that germ that was brought into being nearly a hundred years ago.

The story of plate printing, the second of the three elements in photogravure, and the method of printing by which impressions are produced from photogravure plates, is shorter and much less revolutionary. It is still in about the same state that it has been from its infancy. The same laborious, painstaking method of working is used as at first, and just about the same style of press. That other method of printing, type printing, starting later than plate printing, has sprung up and has grown from the old Caxton handpress, printing a few hundred copies a day, into the modern power machine producing twice as many thousands an hour. Lithography has been born and grown to its present strength, but the old copperplate press has not moved. No means have yet been devised to do the work of the ball of the hand, and just as assuredly no results have been obtained approaching the exquisiteness of the steel or copperplate engraving.

In plate, or steelplate, or copperplate printing, the design to be printed is cut or incised into the surface of a steel or copperplate. This plate is dabbed all over with ink, which fills the incised lines and covers the surface as well. The ink on the surface is wiped off, with cloths and the hand, leaving only the ink in the incised lines. Paper placed on the plate, after heavy pressure has been applied to the back of it, when lifted, withdraws the ink from the lines, leaving the design, which was on the plate, adherent to the paper.

The most probable origin of the art of printing from metallic intaglio plates is that which is attributed to the early Italian workers in niello or inlaid modelling work, an art used for ornamenting table utensils, swords, armour, &c.

ERNEST EDWARDS.

(To be continued.)

HINTS ON COMPOSITION AND SELECTION OF SUBJECT.

[A Communication to the Philadelphia Amateur Photographic Club.]

AN important element of success in the pursuit of landscape photography is the attainment of the power of selection. Those persons who are naturally gifted with that kind of taste which enables them at once to perceive those combinations and effects in nature which will make the most agreeable or effective pictures are indeed fortunate, and although they may receive much gratification and instruction from looking at the works of eminent artists, and seeing under what effects they have treated the various scenes represented by them, such study is not so much a matter of necessity with them as with those who have been less favourably endowed. Sir Joshua Reynolds says: "Nothing is denied to well-directed labour; nothing is to be obtained without it;" so that none of us need despair of attaining excellence if we do but give our earnest attention to our pursuit.

Hundreds of views are constantly being made that are of no account whatever, except inasmuch as they may be pictures of places possessing interesting associations to those who are taking them; as we see in show-cases innumerable faces, admirably done, and each one highly interesting to self and friends, but passed over with the utmost indifference by everybody else. When the object becomes the making of a picture, the producing of a work which, from its possessing certain intrinsic qualities, giving it a wider interest, and ranking it as a work of art, more or less, it is necessary that we discriminate between the beautiful and commonplace in nature. It will not then do to set our camera up in the first country road that we come to and focus straight along it, being satisfied with its parallel sides, lined with stiff fencing and rows of straight-stemmed cedar

trees. We must go further and see if we cannot find a spot where nature will spread before us some of her unfettered charms. Trees, remarkable either for the lightness and grace which characterises some varieties, the fullness which marks others in the vigour of maturity, or for the picturesque ruggedness of decay; some sheet of water, even though it be not river or lake, where we will get mirrored reflections, sparkling lights, and flat, quiet masses of shadow. If we can get a mountain peep in the distance, how fortunate; if not, perhaps we can find a rolling country, dotted with receding masses or groups of fine foliage. And our foreground, let us, if possible, secure some variety in it. Bare earth varied by patches of vegetation, rocks, stumps, and old logs, rather than flat, unbroken stretches of either grass or earth.

Having arrived at a point where we have found some elements of a good picture, let us so compare them by moving from point to point that we get our distance open, and our main groups on either side; but let the group of one side be more important, if possible, than that of the other. There is nothing which makes a more picturesque contrast than a fine, full mass of foliage balancing some quaint, denuded stem, festooned with vines. Our foreground should have some important feature of interest, either suitable figures, cattle, or something striking in form, or light and dark, and not precisely in the centre, but generally a little to one side or the other. It is seldom that such points can be put down in the extreme corners with good effect, as they carry the eye out too far from the centre of the work. Although the plan of composition is occasionally tried by landscape painters of placing the principal group of trees in the centre of the work, it is seldom successful, the open spaces of distance, seen upon either side, equally arresting the attention, and so dividing it that the work is robbed of that unity of impression which should go towards making it agreeable.

There is at the present time a prevailing want of interest in and sympathy with the good art principles seen in the works of the eminent landscape painters who were living and working during the first half of this century, and it is chiefly the outcome of Ruskin's pre-Raffaellite movement. This school and their adherents strove to attain certain sentimental qualities which scarcely belonged to the province of art to convey, and the only art quality which they perfected was that of imitation, which is considered the lowest quality of art; and as genuine pre-Raffaellism was dying out, the great period of scientific investigation set in, turning the minds of reading and thinking people in the direction of materialism and research; and the consequence is that now a picture is not valued as a piece of beautiful colouring, or composition, or effect, as it was formerly, but it must tell some story, or be a wonderful piece of imitation of something, it matters not much what.

Many pictures that are painted now have so little true art in them, and are so solely dependent upon the incident they represent for their aim, that a simple pen sketch would fulfil their purpose just as well as the painting. I think this is somewhat to be regretted, and I hope that a taste may grow up again more in sympathy with true art. Turner, Stanfield, and the many good landscape painters who were working contemporarily with them, seldom, if ever, dealt with nature in her commonplaceness. They sought her out in the picturesque and the beautiful, and did not scruple to gather together what was near and characteristic to a neighbourhood to enrich and beautify their compositions; they delighted in the effects of storm and cloud and sunshine, which give grandeur and poetry to a scene; and I was going on to speak of their colouring, but this we have nothing to do with. When we can fix the image as seen on the focussing screen, colouring included, as we do the light and dark alone, the painter's occupation will indeed be gone.

As we must confine ourselves exclusively to composition and effect, let us consider a few of the first principles to be looked after in the successful getting up of a picture. Working, or rather presenting our subjects as we do upon a flat surface, every artifice should be used to overcome this perpendicularity of plane, and have the effect of leading the eye into the picture. Judicious composition and a proper amount of atmosphere are great aids in the retiring of distant objects and the advancing of nearer ones.

A picture in which a number of conspicuous objects come one over the other, or successively one under another, must appear flat, and especially so if the objects just touch or cut upon one another, and it must to a great extent be by the lightening of shades that we get a distance to recede into the picture. In a landscape reproduction, where our shadows are as black in objects miles off as they are in the immediate foreground, claiming an equal attention, we can get no retirement, and by cutting definitely and harshly against the sky in every part a disagreeable hardness is given to the picture. As a means of obviating this hardness, in addition to working during a prevalence of atmosphere or haze, I would recommend, whenever possible, the introduction of skies, either by printing in or by washing on the back of the negative with a little opaque. When the sky in the negative is not too dense the latter plan will answer very well, and the addition of a sky to a landscape view is of immense value not only on account of breaking up the flat blank space, but it may be made the means of completing the composition of the work; it also serves to carry off the distant features gradually, and repeats the dark tints of the foreground. There are, however, two conditions when skies are better left out; the one when they are got by laying cotton indiscriminately, and the other when printed in from negatives that are too

strong and too bold in their masses, and either overpower the subject of the picture completely, or else divide the attention too much with it, and thereby rob it of its precedence.

XANTHUS SMITH.

(To be continued.)

COMPOSITE PHOTOGRAPHS.

An interesting craze in photography is the effort to produce what is called the "composite" photograph. This means a succession of photographic impressions imposed one upon the other in the same plate, so as to produce in a single picture the combined likenesses of various persons. For instance, three or more people are to be "averaged," so to speak, upon the sensitive plate. First, one is posed before the camera, in direct front or profile view, for such a fraction of the time as would ordinarily be given to one sitter as may represent the number of persons to be photographed. If three persons are to be represented, and the full time of exposure would be six seconds, the exposure for the first one of the three would be exactly two seconds. He now steps aside, and the second one is adjusted to the head-rest, and, when accurately placed, he in turn gets a sitting of two seconds, and so with the third or fourth. Each one who sits before the camera represents his proportion of the full time required. So, in the case of twenty, the instrument must be so stopped down and the light so arranged that, if used upon a single sitter only, the exposure would be twenty seconds. Of course the exposure to each one of the twenty would be one second. Recently I made one of these composite pictures of nine young ladies, members of a literary club. The result would certainly indicate a high average of intellectual ability, if there is anything in the teachings of physiognomy or phrenology. My method of working is different, and, I think, much more simple than that followed by others, as the result is obtained in one operation. As I understand the previous methods, each person has been photographed separately, and from the negatives a transparency has been made, and these each in turn copied on to one plate. I see no reason why the members of the composite should not be photographed directly upon the plate. My method for securing this picture was to so reduce the power of the light as to make necessary an exposure of eighteen seconds. As there were nine sitters the *pro rata* exposure was two seconds. Of course it required great care to superimpose exactly one image upon another. It was accomplished as follows:—I first drew upon the ground-glass a fine perpendicular pencil line, which served as a central line to the head. Across and at right angles to this line I drew two others, an inch and a quarter apart, one of which ran through the line of the mouth, and the other through the eye at the caruncula, or at the joining of the upper and lower cartilages. These lines were arbitrary, and the image was adjusted to them. Of course there is quite a variation in the distances between these two lines in the human head, therefore the camera had to be carefully adjusted after each exposure. As it was very difficult to do this by hand, I constructed adjustable boards hinged at one end, with fine screws, so placed under the camera as to elevate or depress it, and another screw to move the whole camera and bed plate forward or backward, until these distances between the eyes and mouth were made to correspond with the standard. I then made a pendulum by a weight on the end of a string, about forty inches long, practically giving one second to a motion or oscillation. This I found more practicable than a watch. Starting my pendulum, the impressions were made in quick succession. Of course the slide was returned to the holder after each exposure, and a new focus or adjustment of the succeeding sitter made. The only modification to the final picture consisted in uniting the white collars or neck-wear into one. I think it would be best in future experiments to have a dark or black silk kerchief with which to cover the white neck draping, which would give a simple, uniform effect to the upper part of the body.

In the pursuit of these experiments some curious developments occurred. At first I made the natural mistake, I think, of not taking into consideration what one must call the *momentum* of the sensitive particles from the first blow or stroke of the light. There is on the unexposed plate what the scientists call atomic inertia. On the first exposure this is in a degree overcome, and the particles of the sensitive compound receive motion from the impact of the light, which is continued to a degree after the cessation of the exposure. The apparent effect, of course, is to increase the sensitiveness of the plate, so that the exposure should not be equal on the successive subjects, but each exposure should be less than the initial one.

This overcoming of the atomic inertia is to me an explanation of the curious fact that instantaneous photographs were made in the old days of the wet plate process, when the plates were not one-fiftieth as sensitive to the action of a dim or subdued light as the present gelatino-bromide plates, when they were exposed to brilliant light.

For instance, successful photographs of waves in motion were made more than twenty years ago, under the illumination of the broad noonday sun, which would not be over exposed on the present super-sensitive plates. Yet in a subdued light the wet plates were in many instances unavailable where the bromide plates would now record a quick and successful picture, or, in other words, the later bromide plates are more

successful to feeble rays of light than the wet; but in brilliant lights there is comparatively less difference in the sensibility. Hence, I think the stroke, blow, or impact of the bright ray overcomes this atomic inertia, imparting a momentum to the sensitive particles which continues after the light is closed.

Now, if this be so, is there not a liability to error in experiments in this line? While I believe that in the picture of the young ladies' club, a fair and characteristic "average" is presented, I can readily see how one of the young ladies with round, smooth face, blonde complexion, and flaxen hair, could, if not guarded against, have neutralised the impression of all the rest, if they were of a darker style. As I have intimated, after the sensitive film has been decomposed by the action of light—by the reflection from white or light objects—it cannot be undone or modified by any exposure upon dark objects. So, if one should take a series of impressions from aged persons with faces full of lines and shadows, a fair young face would fill in all these shadows, and it matters not in what order it comes. If the smooth, white face makes its image in light, the faces full of shadow will not change that result. To demonstrate this, I first made a composite picture of a number of middle-aged persons, and, finally, took an equal (*i.e.*, proportionate) exposure from a child's face. The average of the faces is not fifty years, but apparently much younger. Now, while this does not prove that an average cannot be made, it does show that the greatest care must be taken to prevent one face from producing a paramount effect upon all the others. A simple illustration of this is that, although one only of the young ladies in my group had light trimming on her dress, it made itself quite apparent in the picture, although all of the rest wore plain, dark dresses.

GEORGE G. ROCKWOOD, in *Art Amateur*, N.Y.

WINFIELD MANOR IN DERBYSHIRE.

[A Communication to the Derby Photographic Society.]

THOUGH these ruins have enough of beauty in themselves to please the photographer, yet I have thought a little information regarding their origin and past history cannot but enhance their attractions, and with this view have put together the following notes:—

Winfield Manor, fourteen miles from Derby, is perhaps one of the finest memorials of ancient architectural splendour we have left, and though shorn of its glory still presents to the appreciative eye many points of beauty worthy of the canvas or the camera. To the poet, historian, or archaeologist, the ruins of this fortified mansion are full of interest, carrying him back to scenes of chivalry and feudal power. I must only glance at its past history; its present condition you have had ample means of studying and enjoying.

Winfield Manor boasts of a green old age, and we know but little about it till the time of William the Conqueror, who gave this, with other manors in Derbyshire, to his natural son, William Peverel. Robert de Heriz, earl of Brittany, held the manor under Peverel, and it continued in the possession of this family for many generations after the flight of Peverel and the forfeiture of his lands to Henry II. Richard de la River married the heiress of the Heriz family, and was the next owner, and his daughter, Margaret, became the wife of Roger Bellars, sheriff of Nottingham and Derby in the reign of Edward III. Their daughter, also named Margaret, married Robert de Swyllington, knight, and her father gave her the manor of Winfield with other lands of her mother's. This last-named pair having no offspring, it was found by an inquisition taken at Derby, Oct. 25, 8th Henry VI., that the property belonged to Ralph, Lord Cromwell, of Tattershall, descended from the Bellars family, and cousin of Margaret, wife of Robert de Swyllington. A lawsuit was instituted, which ended in a compromise, the manor of Winfield remaining in the possession of Lord Cromwell. This Lord Cromwell was a man of great importance in his day, holding many high and lucrative offices. He set to work building this magnificent place on the site of a more ancient structure. It was, however, completed by John Talbot, second earl of Shrewsbury, to whom he had sold the reversionary interest in the manor, and in whose family it remained till 1709.

Four and a half centuries have passed since these walls were raised, and yet they are as strong as ever where time only has affected them. But war and wanton destruction have been at work, the marks of cannon balls can yet be seen on the walls, and the hideous house in the valley below was built from the ready-worked stones of this structure.

In 1569, Mary, Queen of Scots, was brought here, a prisoner, from Tutbury Castle, where she had resided for more than a year previously, a prisoner of state, in the custody of George Talbot, sixth earl of Shrewsbury, the fourth and last husband of the celebrated "Bess of Hardwick." For nine or ten years was the beautiful Queen of Scots in the care of this Earl at divers places, and between his jealous wife and Queen Elizabeth he led a most miserable life. The memory of the hapless Queen will haunt the mind as one wanders amongst these ruins grey and ponders over the times of old: how she and her maids spent their time in needlework, when "the diversity of the colours made the work some lesse tedious;" how attempts were made to liberate her by young Anthony Babington of Dethick and other conspirators, who met at his house only four miles away—of their failure, trial, and barbarous execution.

These plots of Mary's friends hastened the time of her own mock trial

and execution, for Elizabeth deemed her life and throne insecure, and was thus led to sign the death-warrant which will ever be a blot on her memory. No less than two hundred gentlemen, yeomen, officers and soldiers were employed in the custody of Mary at Winfield. Her own establishment at this time included five gentlemen, fourteen servants, three cooks, four boys, three gentlemen's men, six gentlewomen, two wives, and ten wenches and children. They consumed a large quantity of wine, and no wonder her guardian was embarrassed in providing for so large an addition to his household. The suite of rooms on the west side of the inner court, and connected with the great tower, are said to have been those occupied by the unfortunate Queen.

During the civil wars Winfield Manor was the scene of many struggles between the Royalists and Parliamentarians, and several hotly-contested engagements took place—first one party and then the other gaining the ascendancy. In the last siege Sir John Gell planted his cannon on Pentridge Common, on the opposite side of the valley, but could not effect a breach. Coming within nearer range, and being strengthened by a division of the Earl of Manchester's army, the gallant defenders were obliged to surrender, their Governor, Colonel Dalby, having been killed during the conflict. On the 23rd June, 1646, an order in Parliament was issued directing that the place should be dismantled, and from this time it was allowed gradually to fall into decay, the dilapidations which strife had effected being hastened by some who looked on the pile only as a heap of quarried stone, to be used as required for any and every purpose. The sun dials you see about the ruins were placed there by Emanuel Halton, who purchased the manor in 1678. He was a man of studios and retiring habits, pursuing the studies of music, mathematics, and astronomy. He took up his abode here, and did not scruple to pull the place about to make it to his own liking. A successor of his did far worse in removing the stones to build the ugly house I mentioned before. The ruins are, however, now carefully preserved from further demolition, and will long remain to adorn the landscape and afford interest to the antiquary and lover of history, subjects for the painter and photographer, and pleasure to the thousands who seek for recreation in visiting the ancient landmarks of their beautiful country.

Once—

"These now deserted rooms were wont to ring
With laughter and the bacchanalian song,
And startled echo flew from wing to wing,
Repeating sounds of mirth with mimic tongue."

Now—

"These spacious rooms are silent as the dead:
Without a sound my footstep lightly falls;
A grassy carpet on the floor is spread,
And echo slumbers not in roofless walls."

I have made my sketch as concise as possible and have not attempted any description of the ruins by which we are surrounded; their great artistic beauty you will all acknowledge, but should any of you wish to know any more about the building itself, I will gladly be your guide.

PATENTS COMPLETED.

AN IMPROVED PORTABLE PHOTOGRAPHIC APPARATUS.

No. 11,365. HENRY JOHN COOKE, 7, Westminster Chambers, Victoria-street, Westminster.—*September 7, 1886.*

UP to the present time all instantaneous photographing apparatus have been called portable, but none have really ever fulfilled this object, as they have necessitated a great paraphernalia, such as stands, &c. The best way to describe the disadvantages of these apparatus is, that the operator is unable to hide from the public gaze what he is about to do, owing to the quantity of apparatus he is obliged to carry about with him, and he is immediately recognised as a photographer. Another inconvenience of the old apparatus is that before taking a photograph the operator is obliged to arrange the focus, or when desirous of photographing a moving object it is impossible to adjust the focus before the object has changed position or has disappeared, so that it is impossible to fix the object on the sensitive plate. Independently of the weight and size the difficulty has hitherto been to make a portable apparatus which can be carried without attracting attention, and to take instantaneously either moving or fixed objects without first having to arrange the focus. It is this perfected apparatus that I have invented, and which is essentially portable, weighing as it does little over 1 lb.; it can be carried by a strap in a similar way to a field-glass, and can be handled just as easily, or it may be worn under the waistcoat, the lens serving as a button, being so carried as to leave both hands perfectly free. Its speciality is in taking groups in action, figures, birds, facial expressions, and all studies in animal life, where opportunities to sketch or to set up an ordinary camera and arrange the focus are out of the question, making it, therefore, invaluable to artists, engineers, police, and tourists.

My Improved Portable Photographic Apparatus is composed of a metal disc about six inches in diameter and about one inch thick; when preparing to use it the object glass or lens is fixed on one of the sides.

The disc is made in two parts, fitting closely one into the other. The first part contains inside the mechanism of an instantaneous moving shutter, moved by a slight rod worked by pulling a knob on the outside, which is unclinked

by pressure on a second stop-knob or cheek. The second part contains the interior, the sensitive plates for taking the photographs, which may be five, ten, or any other number, according to the diameter of the apparatus or the size of the photographic plates which are put in the apparatus. For instance, in the apparatus which I more particularly describe later on there are five plates. The space where the sensitive plates are placed is shut in with a ring, which can at will be moved from right to left, or *vice versa*, so as to substitute a fresh sensitive plate for the one used in taking an object.

This operation having been done, and plate No. 2 having taken the place of plate No. 1, the next thing is to arm the shutter system, as I have already described, and to lower the central ratchet in the direction of the rod, which is fitted with a spring, so that the apparatus is again ready for work, and you can sight the object you wish to take, letting the apparatus be in such a position that a line passing by the spring rod, the centre of the apparatus, and the objective, shall be vertical to the ground; all that is then necessary is to press the restraining knob so that the object fixes itself on the sensitive plate. The same process is continued until all the plates held in the chamber have been used in succession. Care must be taken that when changing the plates the central ratchet be brought back to the horizontal.

This ratchet moves an interior plate which comes and stops the shutters and allows to present successively the plates to the objective without permitting the light to spoil them. Were this detail forgotten and the sensitive plate allowed to come into contact with the light they would be spoiled. When the first chamber, full of plates, is exhausted, it can be removed from the disc and another substituted. It depends on the operator how many plates he chooses to take with him. These operations once made there is nothing further to do than to take out the sensitive plates used and to make them undergo in a dark chamber the ordinary process of photography.

[Here follow the details of construction, illustrated by diagrams.]

IMPROVEMENTS IN THE MANUFACTURE OF SODIUM SULPHITES.

No. 11,518. JOHN MARTIN COLLETT, High Orchard, Gloucester.—September 10, 1886.

This invention consists in the manufacture of a new form or condition of sulphite or bisulphite of sodium, differing from that ordinarily produced in being amorphous, anhydrous, or nearly so, and practically unchangeable in the air.

I procure this salt by treating dry hydrate of sodium, either in lump or a powdered state, with sulphurous acid gas, this latter being prepared by any of the usual methods.

I place hydrate of sodium, as above mentioned, in a suitable vessel provided with a stirrer or apparatus for moving it about, or the vessel may be made to revolve, and I pass in sulphurous acid gas until the base is converted to the sulphite or bisulphite as required.

The claim is:—Certain improvements in the manufacture of sodium sulphites, as above set forth.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, July 28, at the adjourned annual general meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. J. Traill Taylor presided.

The HON. SECRETARY, Mr. J. J. Briginshaw, then read the Annual Report, as follows:—

Another year has passed in the history of the Association, confirming a further period of usefulness and prosperity, proved by the well attended meetings each week, the steady accession of members throughout the year, together with the balance in the hands of your Treasurer.

Although no new photographic process has been developed during the past year, the applications of photography are so manifold, and the experiences of its workers so varied, that subjects for debate and discussion are regularly brought forward at each weekly meeting, and, however apparently unimportant the subject may appear, receives an equal share of attention with questions of larger import, the most trivial subject frequently leading to interesting and instructive debate. How much of the enormous advance photography has made of recent years is due to society discussions and organization is not easy to determine. Photography, as a veritable handmaid to nature, science, and art, now plays no unimportant part in everyday life. Frequently a natural desire arises on the part of the tyro for a more extended and intimate knowledge of the chemical changes and combinations which take place at every stage of development. It is here that a society of this kind fills the want thus created; a commencement with a "hobby" often leading up to the study of the higher branches of science and art, may be directly or indirectly traced to the instrumentality of society discussions.

During the past season many excellent and interesting demonstrations have been given and papers read. Among these, Woodbury Films, W. K. Burton; Collodio-Bromide Transparencies, J. B. B. Wellington; Development of Collodio-Chloride Prints, J. Hubert; Stripping Films, W. K. Burton; Platinotype Printing, F. W. Edwards; Isochromatic Photography, J. B. B. Wellington; Stripping Films, Buchanan Wollaston; may be enumerated from the members; while from a visitor, Mr. E. J. Palmer, of Toronto, must be recorded an exceedingly ingenious plate coating machine shown in working.

It is always a pleasing duty to recognise favours conferred. To the proprietors of THE BRITISH JOURNAL OF PHOTOGRAPHY, THE PHOTOGRAPHIC NEWS, ANTHONY'S BULLETIN, and THE PHOTOGRAPHIC TIMES, the best thanks of the members are due for their respective publications regularly mailed to this Association.

The most notable incident of the past year has been the formation of the Photographic Convention of the United Kingdom, which has been attended with the happiest results, and is destined to have a direct influence in the advancement of photography. Being associated and interested in its development and progress, the members of this Association may look with pardonable pride upon a movement that gives every promise of leading to many important results.

An exhibition of pictures taken by members during the Convention was subsequently held. Between two and three hundred prints were exhibited. These were chiefly in platinotype and silver. Paper and glass negatives, together with stripping films, were each represented, and afforded ample opportunity for an examination side by side of the results from these several processes. The exhibition proved very attractive, and created a considerable amount of interest among the members and their friends.

That the future position of photography among contemporary arts and sciences is assured may be gathered from the fact of its recognition for the first time in its history by the British Association last year. The successful meeting of the Photographic Convention held just previously at Derby may, however, be in some measure responsible for this.

The great popularity of the optical lantern remains unabated. It has now become firmly established as an indispensable accessory with all photographic societies. Scarcely a single branch of science or art that does not rely on the invaluable aid of the lantern for illustration. This has not been without its influence in creating a desire for greater perfection of transparencies. The past season has consequently witnessed lantern displays of a very high standard of merit. Periodical exhibitions with the optical lantern and oxyhydrogen light have been held, bringing large attendances of members, at which slides of great technical excellence—the work of the members—were shown on the screen. Keen interest was evinced in the instructive nature of these displays.

The entirely social element of the Association has been fully represented by the soiree and smoking concerts held during the winter season, organized by your Hon. Secretary. The large and enthusiastic audiences attracted on each occasion abundantly proved the popularity and enjoyable nature of these evenings.

The annual dinner, by general consent, was held in November instead of July, as heretofore, and was more largely attended than on any other previous year. Opportunity was taken to present your Hon. Secretary with a very substantial recognition of his past services in the interest of the Association generally. The testimonial—a handsome binocular microscope by Ross—was worthy of the Association and appreciated and valued in every sense by the recipient.

The members have had every cause for congratulation in the past, at the same time the future must not be forgotten. The Association has attained a high position, its proceedings are read with widespread interest, and frequent testimony has been tendered to the general popularity of the Association. This fact alone should make every individual jealous of its good name, and create a determination to work in continued hearty co-operation, by which alone the vigour and interests of a society can be maintained. It is not by mere attendance at the meetings or payment of subscription that the whole duty of a member is fulfilled, but rather by disinterested exertion springing from a deep interest and love for the art-science he is following. Let every member feel that he is to a certain extent individually responsible for the welfare of the Association. Genuine and earnest effort will thus be stimulated; this, with a steady maintenance of good fellowship and generosity in debate, cannot fail to place the Association on a still firmer basis and raise it to a still higher level.

The HON. SECRETARY next read the Treasurer's Report, which showed a balance in hand of £9 4s. 9d.

The foregoing reports were unanimously adopted. Votes of thanks were then given to various English and foreign proprietors of photographic periodicals for free copies of their journals posted regularly to the Association.

The HON. SECRETARY said that at the previous Committee meeting of the Association a Sub-Committee was appointed to revise the Rules, and to bring before the members at the annual general meeting any suggested alterations in the same. It held several meetings, and now advised the appointment of a Permanent Committee to attend to the affairs of the Association, and the major part of the suggested new rules were affected by the question whether such Permanent Committee were appointed or not; the completion of the revision of the Rules was, therefore, deferred until this point was decided. He would move the appointment of the Committee.

Mr. W. M. ASHMAN seconded this.

Mr. W. E. DEBENHAM said that the proposal was a radical change in a society which had worked well; he thought that notice of the proposed change should be given to all the members; he would express no opinion for or against the proposed change.

Mr. A. L. HENDERSON somewhat sympathised with Mr. Debenham's views.

On a division it was resolved that the question should be decided that evening.

Messrs. A. HADDON, DEBENHAM, and COX, objected, on the ground that a decision that evening would be contrary to a rule of the Association, which provided that notice of constitutional changes must be posted one month in advance.

Mr. ASHMAN argued that the motion of the Hon. Secretary was in order.

The motion was carried by a majority of nine.

The following Committee was then appointed for one year, by way of experiment:—Messrs. W. M. Ashman, F. A. Bridge, E. Clifton, F. Collins, H. M. Hastings, A. L. Henderson, A. Mackie, and H. M. Smith.

Messrs. J. B. B. Wellington and J. Traill Taylor were elected Trustees; Mr. A. Haddon, Curator; Mr. W. H. Prestwich, Treasurer; and Mr. J. J. Briginshaw, Secretary.

Votes of thanks were given to the officers of the Association for their work during the past year.

Mr. HENDERSON had noticed that Mr. B. J. Edwards had just patented a cutting board for use when cutting glass plates; it looked remarkably like Mr. Cowan's plan. He (Mr. Henderson) had demonstrated once at that Association how a wire could be used to assist in dividing plates when cutting them.

The HON. SECRETARY read a letter from Professor Stebbing, of Paris, setting forth that he would inquire about the proposal emanating from Douai to hold an International Conference of Photographers in Paris at the time of the Exhibition in 1889. He wished the Secretary to give him particulars about the formation of the British Photographic Convention, as he intended to suggest to the French Photographic Society that some such annual gathering should be held in France.

Mr. A. MACKIE said that at the last meeting he did not state that the name of the Photographers' Benevolent Association had been used without its consent in connection with the Stereoscopic Company's coming Exhibition, but that the names of individual members of the Association had been published in connection therewith without their consent.

The Hon. Secretary passed round prospectuses just received of the coming Exhibition of the Royal Cornwall Polytechnic Society.

The CHAIRMAN called attention to a curious case of flare with a single achromatic landscape lens, due to the possessor having made certain alterations in it which necessitated new positions for the stop to avoid flare. It was a little unusual, he said, to obtain a flare spot with landscape lenses. The best way to discover flare was to have a good black tree in front of the lens, hiding the light pretty thoroughly, and obscuring two-thirds of the plate, but elsewhere to have bright sky; then throw a very black focussing cloth over the head and any flare will be apparent.

The CHAIRMAN said that there were two questions in the box; one was, "Why did not makers back plates?" and the other was, "What is the most severe test for the presence of silver in the whites of finished prints upon albumenised paper?"

In consequence of the late hour the consideration of these questions was adjourned.

Mr. HENDERSON called attention to some little spots which had gradually developed in negatives.

Mr. DEBENHAM said that they were no doubt due to incomplete fixing.

Mr. W. H. HARRISON remarked that once he had asked Dr. Stierlin-Hauser, of Rigi Scheideck, a foretime public analyst to the city of Lucerne, why dry plates were not fixed when they appeared to the eye to be fixed, so that they had to be left some time longer in the hypo. His reply was that the film was swollen with water and to the eye looked transparent, but that when the plate was put under the microscope the undissolved particles became visible, for they were present all the time.

The meeting then broke up.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The usual monthly meeting was held on July 28 at the Royal Institution.—The President, Mr. George H. Rutter, in the chair.

The minutes of the last meeting were read and confirmed.

The HON. SECRETARY called attention to the circular of the Photographic Society of Great Britain in connection with their annual exhibition; he also exhibited Tylar's metal dark slide, which was kindly sent by the maker for the inspection of the Association.

Mr. P. Lange exhibited a series of prints in platinotype, the result of one afternoon's work with his detective camera.

Mr. B. J. Sayce exhibited two prints from the Speke Hall excursion—both taken from negatives on Eastman paper—one an outdoor view full against the sun, the other an interior with thirty-six minutes exposure, and both perfectly free from halation.

Mr. Rutter showed J. Watts's "Bijou Actinometer," which was approved of on account of its portability and extreme cheapness, containing all necessary tables on the lid.

Mr. W. Rogers showed the "Secret or Vest Detective Camera," going underneath the waistcoat, the lens protruding through a buttonhole, which takes six pictures on a circular plate, and is quite unobtrusive.

Mr. B. Boothroyd showed Sargent's shutter, made by Stanley.

Mr. RUTTER read the report of the Lydiat excursion, participated in by nine members, visiting Lydiat Old Hall and Sefton Church, when fifty-nine exposures were made; also of excursion to Stokesay and Ludlow, when only three members took part and made thirty-eight exposures.

Mr. EARP read the report on the Speke Hall excursion, which was attended by thirteen members and four friends.

Mr. A. W. BEER read the paper of the evening—*A Few Old Fashioned Notes on a Modern Error; or, Humour the Plate and Save the Negative*, in which he strongly advocated slow development. He pointed out whilst plates exposed under "perfect conditions" were easy enough to develop, using any plate and any developer, that many plates were lost through the amateur exposing a series of plates under varying conditions and attempting to develop them all in the same manner. He strongly advocated the use of what is known as the American Standard Developer, composed as follows:—No. 1. Three ounces of ferrocyanide of potassium, three ounces of pure carbonate of potash, three ounces of carbonate of soda, thirty-two ounces of water. No. 2. Three ounces of sulphite of soda, thirty ounces of water; and for 10×8 plate, taking dry pyrogallol acid, six grains; No. 2, four ounces; and of No. 1, if the plate is likely to be fully exposed, half a drachm (instead of half an ounce, as usually recommended), and five drops of a ten per cent. solution of potassium bromide. If no development appears in five minutes he adds another half drachm of No. 1, which in nineteen cases out of twenty will cause it to progress "quietly and sedately." If after five minutes more it is not sufficiently dense it might have another half drachm; but, above all things, "Don't hurry."

Some discussion arose on the question of using "dry pyro," several members affirming that properly made "sulpho-pyrogallol" would keep good any reasonable length of time, and was more convenient to use. It was pointed out that instances of pyro made up with sulphite of soda going black were due to alkalinity, and that if the solution were made acid it would keep.

Mr. BEER, however, thought that in any case the solution was uncertain, and that dry pyro went farther in development than pyro in solution.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

The monthly meeting of the above was held at the Technical Schools, Bridge-street, on the 28th ultimo.—Mr. W. J. Harrison, F.G.S., in the chair.

The minutes of the last meeting having been read and confirmed, the following gentlemen were elected members of the Society:—Messrs. A. Atkins, G. Baxter, C. F. Jarvis, and R. L. Wareham.

A number of exhibits were shown, including prints, &c., from Messrs. Harrison and Reilly, the former of whom showed Scovill's whole-plate camera fitted with the Eastman roller; Mr. Hiffe, a capital washing tray, by Wakefield; and Mr. Reilly, a very useful combined rule, square, and spirit level.

The CHAIRMAN gave a lengthy and interesting account of the Glasgow Convention, and highly praised the arrangements and reception he received during the week he was at Glasgow and Edinburgh, and hoped the members would

combine to give the Convention a hearty welcome to Birmingham next year, and endeavour to make it a genuine success.

The meeting terminated with the announcement of the excursion on August 1 to Chepstow and Tintern Abbey.

DERBY PHOTOGRAPHIC SOCIETY.

THE members of this Society had an excursion to Winfield Manor on Saturday last under the able leadership of Mr. Richard Keene, who read a most interesting and instructive paper, giving the history of the Manor House (see page 493), which is a magnificent old ruin, for which he was accorded a hearty vote of thanks. There was a good number of members present, and about thirty plates were exposed, after which the party adjourned to the farmhouse adjoining and developed a goodly number of plates (of hair and eggs, &c.) and then returned to Derby.

The next excursion will be to Norbury, on Saturday, August 6.

Correspondence.

THE EURYSCOPE.

To the Editor.

DEAR SIR,—In your last week's issue you published a letter from Messrs. Voigtländer & Son, of Brunswick, addressed to Messrs. Marion & Co., in which the first-mentioned firm charge us with "daring to usurp the word 'Eurycope'"—at the same time Messrs. Voigtländer & Son claim the word as their own upon the strength of having employed it since 1877.

We unhesitatingly say the accusation is not merited, since we have no wish to usurp the term, but regard it as one which has been applied to lenses of a particular type for many years past in this country.

Mr. John Browning, the eminent optician of London, informs us he has used the term "Eurycope" for the last sixteen (16) years or more.

Mr. J. J. Atkinson, of Liverpool, universally known as an authority upon the history of photographic instruments, says: "I have been familiar with the name 'Eurycope' in connection with photographic lenses, other than Voigtländer's, for over twelve (12) years."

The word "Euryscopic" has been marked upon instruments in our own establishment for many years past.

After reading these facts we think Messrs. Voigtländer & Son will unite with us in regretting the publication of their letter, for it is evidently not Perken, Son, & Rayment who have "dared to usurp the word 'Eurycope,'" but Messrs. Voigtländer & Son who have dared to attempt so to do.

In advertising "Optimus" Euryscopes, none genuine unless bearing registered trade mark, Messrs. Voigtländer & Son state that we desire to deceive the public and mask our design. Our design is to call the attention of the public to the "Optimus" Eurycope as distinctive from the Eurycope of any other mark, and that there may be no possibility of deception we long ago registered the word "Optimus" in England and abroad.

A controversy arose on Messrs. Voigtländer & Son claiming the parentage of the optical form of this lens, the outcome of which proved that the laurels for the invention rested on other brows. It may be unpleasant, still it is true, that this second claim of Messrs. Voigtländers to the name "Eurycope" is equally unwarrantable. We feel confident that you, Sir, took part in the controversy referred to. Though we have not the honour of your intimate acquaintance, may we venture to invite you, the veteran Editor of photographic journalism, and intimately acquainted with the history of construction and of nomenclature of lenses, to give the public the benefit of your knowledge and experience on the subject under discussion? We will thank you to make this reply public by inserting it in your next issue.—We are, yours, &c.,

HATTON GARDEN, London, August 3, 1887. PERKEN, SON, & RAYMENT.

[Owing to our receiving this just before going to press we shall defer any remarks on the subject till next week.—ED.]

WASTE GLASS.

To the Editors.

GENTLEMEN,—You remark in last week's JOURNAL that many photographers must be in the same position as your correspondent "W." with reference to a stock of useless glass. I was in the same position until one day I determined to utilise it. I had it all cleaned—something for the gardener to do on a wet day, and designed places so that the sashes would exactly suit the glass. The consequence is that I have now a conservatory 21×14 feet entirely glazed with 10×12 plates, my hot-house with 8½×6½, and my enumeber and melon frames with half-plates. If, by any chance, a pane gets broken, it can at once be replaced without sending for the nearest glazier, who lives five miles away.

If any of our fraternity, who cannot make the same use of old glass that I have done, are desirous of finding a recipient for it, I should be most happy to pay carriage and increase my number of greenhouses, &c.

Another correspondent complains of scratched lines on his burnished prints. Has he tried using a chain burnisher? After use polish clean with a silk handkerchief.—I am, yours, &c.,

Thurning Rectory, Oundle.

J. CARTER BROWNE, D.D.

THE STEREOSCOPIC COMPANY'S EXHIBITION.

To the Editors.

GENTLEMEN,—I am reported to have said at the meeting of the London and Provincial Photographic Association of the 14th instant, that the Stereoscopic Company had not been authorised to use the name of the Photographers' Benevolent Association in connection with their exhibition.

In justice to the Stereoscopic Company, who have so kindly devoted the proceeds of their exhibition to the Benevolent Association, will you allow me to make a correction in the report. I should have been made to say that the Stereoscopic Company had not been authorised to publish the names of the officers of the Association except as officers of the Association in connection with their exhibition. I may add that this was in answer to a question asked at the meeting.—I am, yours, &c., A. MACKIE,
10, Queen's-road, N.W., July 31, 1887.

Exchange Column.

*. * No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Good alpenstock stand, nearly new, for good folding ditto.—Address, C. REYNOLDS, 10, Bolt-court, Fleet-street, E.C.

Wanted, posing chair, three or four changes, and accessories, in exchange for back-grounds equal to new.—Address, W. HUDSON, Bordesley, Birmingham.

Wanted, in exchange for a good 12×10 burnisher, new, a cabinet or whole-plate lens for portraits, in good condition.—Address, J. HETHERINGTON, 42, Blyth-terrace, Gateshead.

Will exchange two 15×12 glass baths, two chonite dippers, and one 10×10 dark slide with two inner frames, for cabinet burnisher.—Address, J. BURDEN, 16, Westfield-road, West Croydon, Surrey.

Will exchange French micro-objective or quarter-plate lens and camera, &c., for quarter or half-plate wide-angle rectilinear lens.—Address, JOHNSON, 2, Cumberland-road, Hanwell, London, W.

I will exchange whole-plate camera, by Hare, and other effects, for half-plate outdoor set, studio stand, or posing chair.—Address, MANAGER, Photographic Works Company, Duston-road, Northampton.

I will exchange Marion & Co.'s eight by eight feet interior background for another, equal value, good condition. Photograph sent.—Address, GRIMSHAW, 16, Dale-street, Haslingden, near Manchester.

Will exchange seven divisions of *History of England*, two volumes of *Encyclopædia*, bound, and other books; wanted, half-plate or larger dark slides or lenses.—Address, BARBER, Gibson-street, Oakes, Huddersfield.

A light half-plate folding camera, with rapid symmetrical lens and mechanical arrangement for slow or quick exposures, will be exchanged for a whole-plate or larger lens (with or without mount), landscape preferred.—Address, W. ROGERS, St. Germans, Cornwall.

I will exchange half-plate bellows-body camera, by Fallowfield, fitted with 5×4 portrait lens, a silver Geneva watch, and small timepiece, for a whole-plate tourist camera with three double slides. Cish adjustment, if any.—Address, GODFREY, 114, Wellington-road, South Stockport.

Will exchange four volumes of Blackie's *Popular Encyclopædia* and forty-four parts of *Virtue's Imperial Shakespeare*, also apparatus for taking portraits by night, with mixture for burning in same, for a 12×10 rapid rectilinear lens or background and chairs.—Address, F. C. D. HURD, Shepton Mallet.

Answers to Correspondents.

NOTICE.—Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a NOM DE PLUME as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

PHOTOGRAPHS REGISTERED:—

W. H. De Lan, Morpeth.—Group of Prince of Wales, Sir Matthew White Ridley, Mr. J. B. Cookson, Captain Terry, and Mr. Dent Dent.

William Henry Loader, 289, West Derby-street, Liverpool.—Photograph of entrance to Newsham, Liverpool.

Williams Brothers, High-street, Rhyd.—Four Groups of the twenty-seven defendants (with their solicitor) charged with rioting.

Thomas Protheroe, 36, Wine-street, Bristol.—Portrait of Rev. F. Freestral, D.D.

T. A.—The bichloride acts upon the whole of the film, supposing there be any silver in it. You can, of course, see the effect.

J. WHITEFOOT.—An article devoted to the subject will be found in the last edition of Hardwich's *Photographic Chemistry*.

J. ROBERTS.—No. 2 position of studio will enable you to obtain the steadiest light throughout the day; next to that would be No. 3.

A. Z. Y.—Unless you require to take pictures in confined situations, by all means purchase a lens of the rapid type in preference to a wide-angle one.

GRFENHORN.—To take hymns for the lantern first make a negative, very intense and of any convenient size, and then from this produce the transparency by wet collodion and the camera.

M. AUTY.—Test the strength of the silver bath and make it stronger if it be required. Judging from the appearance of the prints, one would surmise that the solution was too weak.

F. SMALE.—By shortening the tube and bringing the lenses closer together a larger area of illumination will be obtained, but as the focus will not be shortened to any appreciable extent by this treatment, the dimensions of the image on the ground-glass will be very little reduced.

S. W. wishes to know how he can print from a negative which is cracked, some of the film being also injured. He says that the crack and other injury does not extend beyond the sky.—The best plan will be to stop out the sky entirely with black varnish, so that it prints white; then clouds can be printed in from another negative.

W. HENRY.—The negatives are moderately good as photographs, but you have completely spoiled them in the retouching. If this be a fair example of your skill in retouching you had better confine yourself to operating. If a photographer engages a man as operator and retoucher he naturally expects him to be proficient in both, and you certainly are not.

S. A. WILLIAMS says he has a very badly faded paper print to copy, but the lights are such a strong yellow that he cannot obtain anything like a presentable result. He asks if we can suggest any means by which a fairly good copy can be secured.—If our correspondent will take the negative on an orthochromatic plate, using a yellow screen in front or behind the lens, he will no doubt succeed better, if, indeed, he does not get a very satisfactory result.

S. WATERS wishes to know why some of his unvarnished negatives have a white looking substance upon them at times, and sometimes they are quite moist although they have not been wetted.—Evidently the negatives have been but very slightly washed, hence when the atmosphere is dry the hyposulphite crystallises out, and in damp weather the salt deliquesces on the surface. For this to happen the washing must have been most carelessly performed.

HYPO says: "The hypo in which I have fixed my dry plates and opal enlargements I have collected and evaporated in a jar in the oven. I have now crystals and a black, muddy sediment; do you think there is any silver in the crystals yet? I should be very thankful if you would be so kind as to advise me what to do."—The best plan will be to redissolve the crystals and then add sulphide of potassium so long as any precipitate is thrown down; the "black, muddy sediment" should be added to the sulphide of silver.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, August 10, 1887, will be on *Varnishes and Varnishing*. Saturday outing, if fine, at Hyde Park Corner, at two o'clock. Mr. Cobb will supply a vehicle.

We have received from W. R. Ridgway, Ealing, W., samples of some of the brands of sensitised paper prepared by him. Included in these are plain salted, without being albumenised; together with albumenised, both white and tinted. We found them to print well and yield good tones.

NORTH LONDON PHOTOGRAPHIC SOCIETY.—The next meeting will take place on Tuesday, August 16, and will be a technical meeting. Visitors are invited. Excursions:—August 6, to Hampstead Heath; trains from Broad-street every half hour. August 13, to Wood-street, Walthamstow, for Epping Forest; trains from Liverpool-street every half hour.

HINTS TO AMATEUR PHOTOGRAPHERS.—An important fact to be remembered in making portraits at close quarters is that the professional photographer uses for portraits a special portrait lens, but the amateur generally does this work with a lens made for taking views. These view lenses "condense" very much; that is to say, exaggerate the perspective by taking in so wide a field. Sometimes in taking a simple profile, if the head is placed too near the camera, the visible ear of the sitter, not having a chance to get so far off as the nose—which has, let us say, two and a half inches of an advantage—is given an alarming size. Then in a full-face view the poor nose has the worst of it. On this account a "three-quarter" view is the best for an amateur working with a view camera; though if a fair distance is allowed between the sitter and the lens there need be no difficulty of either sort. Do not hesitate to make experiments. Many of the advances in photography have resulted from the seeming blunders of amateurs. To those who, at college or at home, are engaged in scientific studies the camera will afford a means of interesting experiment. The camera has been one of the greatest teachers of this century. It has, for instance, taught Meissonier, the great French painter, that the horses in his "1807" are not galloping as horses actually do gallop. It has taught the scientist who photographed a flying bullet that the reason the best marksmen cannot hit a suspended egg-shell is that a cushion of compressed air precedes the bullet and pushes the shell out of the way. And in a thousand other ways it has been confirming or upsetting scientific and artistic theories. Let the amateur, therefore, pursue his investigations freely in this field of experiment, and see what discoveries he may make therein.—St. Nicholas.

PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM. HELD AT GLASGOW, JULY 4-9, 1887.

GROUP TAKEN AT TARBERT.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1423. VOL. XXXIV.—AUGUST 12, 1887.

FRILLING TROUBLES.

DURING the prevalence of such tropical weather as has been experienced this summer, we have had so little complaint of frilling that we are inclined to the belief that a steady improvement in the quality of the plates now purchasable must have been continuously taking place for some time past. Some time ago we entered into an exhaustive investigation of this subject, and conclusively showed that in most instances the cause of frilling was the separation from the glass and the swelling of the gelatine through the unequal osmotic interchange of water and salt—"hypo" or otherwise—during developing and fixing operations. We likewise indicated a series of remedies preventive and curative.

A letter in another portion of our columns gives an example of perhaps the most annoying manner in which the evil manifests itself. Everything is going on well, no change presumably in the manner of working, yet, of a sudden, frills set in and peril the very existence of the negative. It is a very easy matter when a stock of plates is laid in to return every one if it is found out in time that they are unduly liable to the evil, as also it is to take remedial precautions when a slight tendency to frill is known to exist. But when, like a thief in the night, the much-feared rucking up of the edge, followed by an ever-increasing lifting of the film, makes its sudden appearance, when hitherto all had been going on satisfactorily, nothing but the promptest action can save the picture from becoming a complete wreck. This is a state of affairs which most photographers have had an experience of.

Now, although, as we said before, we have shown the cause and the mode of prevention, every photographer has his own plan—which usually is alum, alum, alum—these hardly reach the case with which we are dealing, and we must suggest more heroic measures.

We will follow up a batch of negatives which are being treated, say three dishes being employed. Half of them, let us say, have developed as usual; but the next three as soon as placed in the washing water show frilling, which increases every moment, and, after fixing, the whole film slips away. If a dish of alum is not immediately available, the unfixed negatives in the washing water should at once be placed in the hypo fixing solution (no danger whatever to the integrity of the negative is to be apprehended, even if a plate be taken direct from the developing into the fixing solution), which should be diluted till of a strength of not more than an ounce and a half to the pint. It will rarely, if ever, occur that frilling will increase in the hypo; the opposite action rather would take place. The plates should be left in the hypo for five or ten minutes after apparent fixation, and allowed to drain ten minutes—not for

too long a time, or the image will be reduced. Then the plate, after having as much moisture as possible removed by a piece of blotting-paper, should be gently dabbed with a wet cloth, the moisture reabsorbed with dry paper, and then careful washing may follow.

If a negative have only partially frilled after washing following fixing, and an inch or two of expanded film hang over the edge of the negative, which is absurdly distorted at the parts, it can be completely remedied by placing the plate in a dish of methylated spirit. After the lapse of a very short time the most violently expanded film will be reduced to its original dimensions, and during the process of reduction it should be gently pressed into position by the fingers, all air bubbles being pressed out at the same time. In almost any but portrait negatives it will be impossible after the plate is dry to distinguish the portions that have undergone these metamorphosis in size.

It may happen in very bad cases that, notwithstanding all the above described precautions, the negative will "go" after fixing, and it appears hopeless to do anything with the rest, even with alum solution at hand. There is no need to despair even now. Let the next plates developed be placed, after a short rinsing with water, into alum solution; the worst examples are not likely to frill to any further extent in this solution, the object being to thoroughly wash out the developer as a preliminary to the next treatment. The alum solution may then be washed off as well as possible, and the plates, unfixed, be placed in the rack to dry. At this stage, if the developer have been well washed out, there will be no risk in admitting a little daylight into the room; but if circumstances permit, it is well to keep daylight from the plates for fear lest any of the developer remain in the film, in which case we should expect fogged and over dense negatives.

When even the most errant plates are once well dried after developing and aluming, they may be placed in weak hypo to fix, and be washed afterwards without fear of frilling. But we would interpose the words of warning, "Use fresh hypo." In the hurry and confusion attendant upon the unexpected occurrence of the enemy, at, perhaps, a very busy moment, it may be expected that the alum might not be entirely removed; and if this were so, there would be increased danger of want of permanency, for we must remember that the most potent cause of the ills attendant upon the decomposition following the admixture of alum with hypo is not so much the products of decomposition of the two salts as of the deposition in the film of the silver dissolved in the hypo. It is easy enough to predicate the results of this admixture, but impossible to believe that if silver be present it can be "eliminated." It will

remain in the film in a form potent for evil; hence, the fresher the solution of hypo, the smaller the amount of the silver thrown down.

We do not at the moment of writing remember this method of a preliminary drying of impracticable films having before been recommended, and we can say that, having tried the method in our own practice, we have found it to answer admirably with the most imperfect plates we could discover. We have found a tendency in the method to produce too great density of image, but by following the precautions given this may be avoided. Should it, however, be brought about by any failure of operations, a slight treatment with Mr. Howard Farmer's reducer of ferriocyanide of potassium and hypo will bring it right, and in few cases could the treatment be traced in its effects. We have endeavoured briefly to give instructions as to how to proceed in case of a sudden attack of frilling, and, we trust, with advantage to our readers; but our best wish is that they may never have occasion to put them into operation.

SHOULDER SHOTS WITH THE CAMERA.

For pictures requiring instantaneous exposures camera stands are not necessary.

We have proved in our own experience, over and over again, that sharp images may be obtained when holding the camera up with both hands, relegating one finger to the liberation of the shutter by which the exposure is made. We have proved that for instantaneous work the camera stand is of no more use than would be a support for a fowling piece when being utilised in the field in pursuit of game, or anything else on the wing.

A practical application of this is found in the employment of detective cameras, which, when used as such, are invariably held in the hands. Nor need there be any blurring of the image arising from a jar of the shutter or motion of the camera during the momentary exposure. We find upon examining a number of negatives taken in this way that they will bear enlargement (when printed as transparencies) up to twelve or sixteen feet on the lantern disc without any apparent falling off in definition. This does not apply alone to shots made by a properly constructed detective camera, but to any camera when held by both hands and directed to the object to be taken.

We have long since discarded "finders" in cameras of this class as useless. It is not only possible, but, after a little practice, quite easy so to aim the camera that any desired object shall be precisely in the centre of the plate. Let the camera be held up, as shown in the cut, but with the eye glancing along the upper corner, and upon touching the trigger or pressing the pneumatic ball, the object seen, when looking along the corner, will of a certainty be found in the centre of the plate. Suppose the object to be the not very artistic one of a brick wall, one brick in the centre of which is chalk-marked; if the camera is sighted to that and is pointed with such a moderate degree of accuracy as, were the weapon otherwise, would ensure the bringing down of a partridge on the wing, it may be depended upon that the brick thus marked will be in the centre of the field.

Judgment is required at the critical moment to know just how much of a subject aimed at will be included in the view; judgment also is required to determine the proper allocation of the subject on the plate; but this is arrived at by experience.

Weight is a desirable feature in a small camera when taking

views on the wing without a stand. On one occasion we found, when employing a very light quarter-plate camera for instantaneous shots, that the sharpness was not at all what could be desired, although we knew from former experience that the lens could not be at fault. After cogitating the matter over we arrived at the conclusion that the very lightness of the camera was the factor in this impaired definition. So, strap-

ping a weight of over a pound to the bottom of the camera, further trials were made with complete immunity from the evil.

This arises from presumably the same reason that causes a sportsman to say that he can shoot more steadily and better with a heavy than with a light rifle.

It is good initiatory practice in this direction to select a scene in which the horizon is as nearly level as possible, and make a few shots with the special aim of reproducing this horizon line not only straight across the plate, but either a little above or a little below the centre of the plate, at will.

This having been achieved, the next thing ought to be to raise the camera from the side (we assume that it is being carried in the right hand all ready for whatever happens to turn up), and having sighted the object to be taken, effect the exposure and have the camera brought down to its former position in a period of two or, at most, three seconds. When one can do this then may he consider himself qualified for taking snap shots without reasonable fear of attention being directed to his ongoings.

PERMANENT SILVER PRINTS.

ONCE more the subject of the permanency of prints in silver is on the *tapis*, taking the form on this occasion of a question as to the morality of describing a developed gelatino-silver print as "permanent." In the discussion that arose a few months back on the same subject it was pretty generally agreed that the term "permanent" as applied to photographs, or even to engravings, is but a relative one, and that if *absolute* permanency be the requirement no known process fulfils it.

There are, of course, varying degrees of permanency to be met with in connection with different photographic printing

processes, and even with different examples of one and the same process. For instance, some silver prints fade in a very short time, while others are in existence that have withstood the test of thirty years or more. Similarly with carbon and platinotype prints, though supposed to be absolutely permanent so far as the composition of the image is concerned, we are well aware that they not unfrequently suffer deterioration and discolouration. The question of relative permanency must then be considered in direct conjunction with the degree of care exercised in the production of the proof by whatever process it may be executed, and not decided merely by the material forming the image. In this matter developed gelatino-bromide prints in no wise differ from others, and may be supposed to offer chances of permanency in direct relation to the amount of care bestowed upon their production.

How far such prints can be compared with those by other methods is a different question altogether. Clearly, other things being equal, they must be considered inferior to carbon and platinotype, if only on account of the greater indestructibility of the materials forming the image in these two processes. Then, if they are compared with other kinds of prints in which silver forms the basis of the image, a new set of conditions enter into the consideration, namely, the nature of the vehicle or material holding or binding the image together, as well as the condition in which the finely divided metal is found in the picture. The principal media we have to deal with are albumen, gelatine, starch, and collodion, of which the first-named has undoubtedly the worst character, while gelatine perhaps comes next. Then, as regards the composition of the image, we have to discriminate between the metallic deposit formed by the reduction of the sensitive material by means of development and the semi-organic compound formed by the direct action of light upon complex organic salts of silver. Further, we must calculate how far the components of the image are likely to react upon one another under favourable conditions to produce change.

The developed image has long been known to possess comparatively greater stability than that formed by direct printing, and very early examples of calotype and other developed silver pictures are still in existence to show how far the claim of relative permanency is justified. But of course the vehicle holding the metallic deposit must be considered to have some influence on the result. For instance, a plain paper print—that is, one in which the image is formed in and held together by the sizing of the paper—is usually found to withstand the vicissitudes of age and climate far better than one in which the particles of silver are embedded in a layer of treacherous albumen.

Considerable danger is supposed to lurk about a film of gelatine, in consequence of the tenacity with which it is said to cling to silver and other salts with which it comes in contact; hence, in the case of gelatino-bromide or chloride proofs, the necessity for a very great amount of care in manipulation. Hence, also, we may assume that the danger is less in proportion as the quantity of gelatine is reduced; for plainly an extremely thin layer of gelatine, amounting only to another sizing of the paper, will retain less soluble matter than a thick coating which forms a gloss upon the surface. It may be noted that the prints alluded to as having been wrongly described as “permanent” are of the former class—developed prints, with a perfectly matt surface—and may, therefore, if carefully executed, claim as fair a share of permanency as any proof in silver.

We had a few days ago a remarkable instance of the comparative superiority of “plain paper” prints, both direct and developed, over albumenised paper. A box containing prints of the three kinds, more than twenty, perhaps five-and-twenty years old, was turned out of a damp outhouse, where it had been stored with other lumber for at least several years. The contents, printed matter and photographs alike, were damp, mildewed, and rotten, so far as the paper was concerned. The albumenised prints had faded into almost invisibility, but the others showed little deterioration of the image, except where actual mechanical destruction had occurred, and in some few of the better protected cases the picture might almost be said to be uninjured. These prints were made, we were informed, by floating plain paper upon a seven-and-a-half-grain solution of salted gelatine, drying, ironing, and subsequently sensitising by floating on a sixty-grain silver bath. Some were developed, others “printed out,” but at this distance of time it was impossible to distinguish between them, otherwise it would have been interesting to note which had stood the undoubtedly severe test best. At any rate it seems a fair proof that gelatino-silver proofs need not despair of being considered fairly permanent.

AMONGST the Jubilee presents to Her Majesty was a very interesting one from those employed at the Ordnance Survey Office, Southampton. It is a book illustrative of the history of the Ordnance Survey from its commencement down to the present time. It contains drawings, photographs, and engravings, explanatory of the different work carried on by the department. Photography, photo-mechanical processes, and electricity play a very important part at the Southampton establishment. We may mention that even the plates, with the design for the covers of the book, were produced by the joint agency of photography and electricity—the Waterhouse process being the one employed. The present Ordnance Survey Department was formed, we believe, fifty years ago at the Tower of London. Hence it has now arrived at its jubilee. At the time it was started it was a very insignificant affair, as may well be imagined from its location. Now it is a very important institution, and some idea of its magnitude may be formed when we mention that the number of hands engaged at the Southampton establishment alone is between eight and nine hundred.

THE Photographic Club outing on Saturday last was a somewhat novel one. The place of meeting was Hyde Park Corner, and from thence the party journeyed eastwards in a commodious vehicle provided by one of the members (Mr. Cobb), taking flying shots *en route*. The idea was a good one, and is well worth repeating by other societies or clubs who make a feature of Saturday afternoon outings. Some of the most successful instantaneous street views of London have been taken from vehicles; indeed, this is about the only means by which they can be satisfactorily obtained in the busy thoroughfares so that the pictures convey a correct idea of the scene.

AN important case under the Copyright Act of 1866, which has been pending for some time, was decided, on appeal, one day last week. It appears that the plaintiffs, Messrs. Tuck & Sons, employed the defendants, printers in Berlin, to produce a certain number of copies of a drawing. This they did, and also made some more copies on their own account, some of which were imported into this country. The plaintiffs afterwards registered the copyright, yet after this registration the defendant sold copies in England. An action was then commenced by the plaintiffs for penalties under Section 6, and for damages under Section 11. At the trial the jury assessed the penalties at £175, and the damages at £100. The judge, however, ruled that the case did not come within Section 6 of the Act, and therefore gave judgment for £100 only. Upon this the defendants applied to the Divisional Court to enter judgment for them on the claim for damages or for a new trial, on the ground that the damages were excessive; there was also a cross motion for the penalties.

The Divisional Court gave judgment for the defendants on both claims. The case was then brought into the Court of Appeal, where it was decided, by a majority of the judges, in favour of the plaintiff on the question of damages to the extent of £30 only, and that the defendants were not liable for the penalties. The Court, however, granted an injunction restraining the defendants from selling any further copies. From beginning to end this has been an expensive litigation, and it is to be hoped that, when a new Copyright Act is passed, it will be sufficiently clear and explicit so that costly proceedings similar to the above will be avoided.

REMARKS by no means complimentary to the proprietary of the Deal Pier, and their ten shilling toll to photographers, were passed at the Photographic Club last week. We learn that the Pier is not the property of the Town Council but that of a private firm, and that financially it is not a great success. If no notice appears at the entrance to the effect that photographing from the Pier is prohibited unless the ten shilling impost is paid, any one who happens to be unaware of the regulation and exposes some plates can only be requested to desist. Any demand that he should destroy the plates already exposed would be simply nonsense. If any force were employed to compel him to do so, as is alleged to have been done, it would amount to an assault and be punishable as such by the magistrates.

GELATINE as a mountant meets with but little favour amongst photographers, yet, in some respects, it is one of the best materials that can be employed, inasmuch as it acts, to a certain extent, as an insulator from the mount. If that happens to contain any matter which acts injuriously on the print, a layer of gelatine interposing will afford it some little protection. Many photographers who have tried gelatine have met with difficulty in its employment, chiefly arising from the solution setting before the print can be adjusted in its proper position on the mount, hence they have abandoned its use. The mistake in their case has been in the employment of a gelatine of too high a quality, or, perhaps, using the solution too strong. It is next to impossible to mount prints successfully with some of the better kinds of gelatine—those used for dry plates, for example. The kinds best adapted for mounting purposes are those of the poorest quality—as a gelatine—that can be obtained, provided they are pure. One of the best kinds we have used for mounting pictures is Nelson's "No. 2 Soluble." It possesses the quality of setting slowly, is free from acidity, and it contains nothing which is likely to act injuriously on a photograph. It also has great adhesive properties, therefore the solution may be used very dilute—a great convenience. This brand of gelatine is also well adapted, which the higher qualities are not, for making a mountant, in which a large proportion of the water is replaced by alcohol, such as those used to avoid cockling of the mounts.

SOME professional mounters employ glue for mounting photographs, and select those even of the commoner qualities in preference to the better, simply because the solution does not gelatinise so quickly. Glues are all more or less impure from a photographer's point of view, and are, moreover, usually acid. The commoner the quality the greater, generally, is the impurity, hence for mounting silver prints any kind of common glue should be avoided.

COLOURING AS APPLIED TO PHOTOGRAPHY.*

If carefully considered, there will be found to exist a very close resemblance between pure art, if I may so put it, and the photographic art. In the composing, lighting, and general arrangement of the accessories, the same rules should guide us in both cases. The same feeling should inspire the operator in his studio that inspires the artist at his easel.

In all pictures there should be at least one leading or principal light, a point of attraction which will at once catch the eye and to which all others should be subordinate. In portraiture this point of attraction should naturally be the face, as upon it depends the value and interest of the whole picture. Every thing should be subservient to the face, and any obtrusive accessory, or offensively apparent dash of colour

* Continued from page 454.

which may in the least distract the eye from it, may honestly and surely be put down as a fault. Of course I do not mean to say by this that the face must be the *only* point of light and attraction. On the contrary, lights may be repeated in different forms and carried throughout the picture, but in a more subdued degree. They will thus be an aid to the general effect of the picture, giving it life and airiness, whereas without them it might have appeared heavy and dull. Indeed, many a time it will be found not only advisable but even necessary to relieve a large or heavy mass of deep shade by the infusion of a little light; here the artist has another marked advantage over the photographer. The latter is obliged to gain this result by letting in *real* light, be it direct or reflected, and this must in many cases naturally interfere with the rest of his picture. In a picture where a number of accessories are being used, the photographer may certainly so place a certain coloured article that will either naturally catch the light more than the surrounding objects, or whose actinic qualities may produce a different degree of intensity. But, as I say, all this has its various disadvantages. The painter, however, by a judicious blending of colour, will secure the desired effect and still not alter in the least the general tone of his shadow. It is always a serious consideration to keep the deepest masses of shadow from being too heavy, and yet they must be preserved sufficiently dominant so as to impart balance and solidity to the picture.

In arranging a portrait (more especially when three-quarter or full length) care should be taken that the masses of shadow—those portions giving the idea of weight—should be kept at the base or lower portion of the picture. This refers alike to colour as to form. Take for example the production of a portrait of a gentleman, say either three-quarter or full length, and paint or photograph him against a plain background that will present an equal tone all over, the result will be perfectly absurd. An uncultured eye may look at it, say there is something wrong, unpleasant, about it, and still not really detect where the real trouble lies. Well, with such a portrait, let us see what we can do to better it. We know that the standing figure of a man unsupported by accessories must always appear uncomfortable, as the man would in all probability himself feel while giving a *sitting*. This is one of the extraordinary advantages of art, both pure and photographic; a subject can give a *sitting*, *standing*, and may be not untruthfully said to *sit* while he *stands*.

Being convinced, therefore, that a figure so placed is at a very great disadvantage, our task must be to so alter it that it may be satisfactory in all respects. What is required is breadth of base, and this may be secured by the judicious introduction of accessories, or even (in photography) by the placing of a walking-stick or umbrella so as to give the idea of support to the body, which would naturally produce the effect of broadness of base. In the case of the artist this means can not only be adopted with like success, but he can, by the simple arrangement of his darker masses of shadows, so that they naturally find themselves at the bottom or base of his picture, secure that equilibrium or balance which is so indispensable to success.

It must ever be borne in mind that these and all similar effects should be devised and produced in such a manner as not to unduly attract the eye. They must appear natural, not artificial, and must not easily expose the intention of the artist, as, failing this, the advantages gained will be very seriously discounted.

To the beginner or amateur who determines to acquire at least the primary rules for the artistic composition of portraiture, whether in the photographic studio or on the canvas, the *pyramidal* form seems to be the favourite. They think it the easiest, as it is perhaps the least complicated. I have nothing whatever to say against its adoption, but I wish to draw attention to the fact that it requires a great deal of sound artistic skill to treat it successfully. The trouble here is to secure the effect without letting the means by which we gained it become too observable. Now, this at first sight may appear very easy, but, believe me, it is not so, and will give the beginner a deal of worry before he thoroughly masters it. One wants a very keen artistic appreciation to successfully produce this form of composition. Too much attention cannot be given to the study of the various forms of compositions, as at times the numbers and the disproportionate subjects which will come to a studio to be grouped would almost defy a Sir Frederick Leighton himself to realise grace of composition in making a picture of them. I think

the truth of this will be evident to any operator of a few years' experience in the studio.

Contrast is a most important element in every form of pictorial effect—contrast as regards drawing or lines, and contrast as regards tones—both colour and light and shade. The value and grace, for example, of curved lines can not only be made apparent, but absolutely shown to greater advantage, by having straight lines judiciously placed for the purpose. They might be considered somewhat complementary to each other, the straight lines showing off the beauty and grace of the curved ones, while the latter, whatever their good intentions may be, succeed only in showing that their neighbours are *straight*.

Relief, vigour, brilliancy, and general harmony are the results of the artistic contrast and varieties of tones. These contrasts should never be harsh or abrupt. We must not run away with the idea that contrast means in all cases *pictorial effect*. This is not so. On the contrary, it may be even the ruin of a picture. The bringing together of a mass of black and a mass of white, without any attempt at gradation of any kind, will undoubtedly produce *contrast*, but it will be entirely devoid of pictorial effect. One of the most essential qualities in a picture of merit is *breadth*, and this can never be obtained where harsh and crude contrasts are to be found. In the arrangements, therefore, of draperies and other accessories, it should be our constant care to avoid placing such colours (if I may be permitted to call them such for the moment) as black and white in anything like juxtaposition. Both may be necessary and even advantageous to a picture, but their approach towards each other should be marked by such gradations as will thoroughly dispel any feeling of harshness or crudeness which, without same, would be sure to exist.

There is nothing so conducive to the securing of harmonious contrast of tones as the judicious and artistic lighting of the model. Carefully avoid throwing a direct front light upon it, for by such a lighting you would inevitably deprive it of all relief. Generally speaking it is advantageous (unless some out-of-the-way effect is desired) to let the light fall upon the model at an angle of 45°; direct *vertical* light should be avoided, but the freest use may be made of the *side* light. Note should be made that force is obtained by a direct light, while softness and delicacy can only be produced by diffused light. It is not advisable to adopt either as a sole means for producing a picture, but rather by a judicious combination of the two. Form and strength of outline may be secured by the direct light, to which the diffused light will then impart softness and texture. Too much diffused light must not be employed, however, or else the shadows will be weakened, and, as a natural result, a general flatness and tameness will be imparted to the pictures. Indeed, to secure force and vigour in a picture, it is absolutely necessary to combine the two, namely, the direct and the diffused lights.

In half and three-quarter length pictures, many prefer plain backgrounds, that is, without accessory, but so tinted as to produce a deeper shadow at the base than at the top. Without this there would be no balance. Now, although these pictures may be very pleasing indeed, it does not at all follow that a full-length portrait would be the same. No, the full length really wants a help in the way of accessories, &c. In arranging these accessories, therefore, I beg to draw attention to the necessity of their being in harmony with each other and with surrounding objects, as well as with the character of the sitter.

In a lifetime I have seen some strange combinations in this regard. Some, you would say, are absurd, nay, impossible; nevertheless they are there. It was nothing very uncommon some time ago to see in a picture an article of furniture to be usually found in the drawing room apparently located on the seashore. I have often seen a curtain to an open background or seascape. I have seen a lady in evening dress against some snow-capped mountains. Of course all this is bad enough, and now but seldom occurs. There is another stupid but less observable blunder often committed by the thoughtless operator. I now refer to the introduction of such accessories as balustrades, &c., showing a distinct effect of light upon their surface. These oftentimes are placed behind a sitter, and the sitter then lighted from the other side. This naturally spoils the picture, and, I am glad to say, very seldom occurs nowadays, but sometimes it crops up even in otherwise good photographs.

It is advisable to have as great a variety of accessories as possible, both as regards form and colour, for it is only thus that the operator can cope with the exigencies of composition when he has ungainly subjects to deal with. Care should be taken in the use of painted backgrounds to see that the light and shade will correspond with that of the model. There should be no very distinct form visible in backgrounds, as they may often come against a head in a most objectionable position. There should be no distinct pattern on the carpet which would form a series of perspective lines, and it should be dark in tone. I think now we have run through all the preliminary matters which may help us in the colouring, and can now safely make a start in that direction.

A photograph, however good, is still cold and lifeless, but the skilful application of colour gives life and animation to it. It gives an idea of the man's character, his occupation, and oftentimes his mind.

REDMOND BARNETT.

(To be continued.)

THE ACTINOMETER IN LANDSCAPE WORK.

Is the actinometer, as usually constructed, of any practical value to the outdoor photographer? Every now and then we see in the journals a revival of its proposed use, but never so far as I can see are any new arguments brought forward in its favour, but rather the proposals seem to emanate from beginners to whom the idea is new, and who have not devoted a sufficient amount of thought to the subject.

I have confined myself for the purposes of this article to the question of the utility of the actinometer in relation to landscape work only, but I may remark, in passing, that as a scientific instrument it is doubtful whether its value is assured in any capacity connected with photography. I will take its original and perhaps most really useful application, namely, to the timing of the exposures in carbon printing and similar processes, the progress of the formation of the image in which cannot be followed by the eye. Here we have both sensitive surface and actinometer exposed simultaneously to the same direct light, and consequently each receives precisely the same quantity and undergoes the same amount of alteration.

But, on the other hand, there is a wide margin of uncertainty; in the first place, in estimating the tints, whether one or several, everything is left to the judgment of the observer or rather to the capacity of his eye to discriminate nicely in comparing the tint produced with the standard. In the case of those instruments where the exposure is measured by the printing of a certain number of successive tints of no great depth, while it is perhaps easier to secure a tolerably accurate comparison in the case of each individual tint with the standard, still the number of times the operation has to be repeated multiplies the chance of error as well as the actual error if there be any. Where the paper is permitted to darken until it matches a tint upon a graduated scale as in the Woodbury photometer, though there is only one exposure and only one exercise of the judgment, it will be found that not only is it more difficult to compare the darker tints but a very considerable variation may be made in the length of two successive exposures and it shall be difficult to say which tint more closely matches the standard. These difficulties are only increased when, as is the case nine times out of ten, the colour of the standard differs from that given by the sensitive paper employed.

Another trouble, and one which would prove insurmountable were it not for the well-known quality of "latitude" existing in the development of all photographic images, is found in the difference of the light's action upon the two surfaces as the circumstances vary. If the sensitive surface to be timed and the sensitive material employed in the photometer vary in composition, we can hardly regard the one as an accurate measure for the other; by accident, under certain conditions, ordinary silver paper may form an approximate guide for the exposure of carbon tissue, but we cannot expect, nor in practice do we find, the same degree of approximation under every condition of light. In point of fact, though silvered paper in a good summer light may colour almost, if not quite, as rapidly as carbon tissue, the latter in winter is far the more rapid, and therefore the number of tints that suffice in summer would be entirely misleading

in winter; and if this disagreement occur with the seasons why not with the hour of the day? With collodio-chloride, gelatino-chloride, or platinotype, the same objection holds good; the different surfaces do not possess the same colouring power under varying conditions as the silvered paper usually employed in the actinometer. Therefore I hold that even under the most favourable conditions, that is, in direct printing, the photometer is but an approximate guide.

But what shall we say of it when the circumstances are wholly changed and the measuring instrument is exposed to direct light, while the image is formed upon the sensitive plate in the camera by the rays of the same light reflected from an innumerable variety of surfaces? If we try to improve matters by exposing the actinometer to reflected instead of to direct rays, which shall we select? The shadows, the lights, or the *tout ensemble* of the landscape? And how are we to do it? Then, again, we shall have not only to replace the slowly colouring albumen paper by something more nearly approaching the sensitiveness of the dry plate, but, further than that, substitute development for direct printing if we want to get any degree of accuracy. In fact, in order to meet the requirements of the case, we want a sort of camera that will condense the light reflected from any particular portion of the object, and throwing it on to a sensitive surface similar to, if not identical with, the plate to be employed, enable the operator with the aid of a more or less arbitrary method of measurement, by graduated screen or otherwise, to estimate the exposure necessary for *that portion only* of the subject tested. But what about the rest of the picture?

The fact seems to be that the supporters of the actinometer entirely overlook several things, and can only bring one or two items of evidence to support them. The actinometer gives you, they say, an idea of the value of the light at the time, which, of course, must be an advantage. Perhaps so, if the experience of the operator be insufficient to give him an idea that is at least as free from liability to error as the subsequent operations with the actinometer. But with that estimate of the power of the light the functions of the instrument cease; everything else is really as much left to the judgment of the photographer himself as if the actinometer had been left at home. "But," say they, "the proof of the pudding is in the eating; we can accurately time our pictures by means of the actinometer."

Perhaps they can; but perhaps they would do it just as well without. There is no necessity to blame the actinometer for the result. Perhaps the latitude of exposure of dry plates, perhaps the great latitude in development of the same, may have something to do with it; and perhaps the extra care in manipulation generally, born of the knowledge that they have a "fad" to prove, may have as much to do with it as all the rest put together.

If the exposure of a gelatino-bromide plate had to be made within a small margin of absolute accuracy in order to obtain a result, and development consisted in merely immersing it for a certain time in what is called a "normal" solution without any modification whatever, I should like to see the gentleman with the actinometer at work. They would, I fancy, very soon find that unless they exercised their judgment in the matter of exposure the trusted instrument could tell them nothing. If all subjects were alike, and all "open landscapes with foliage" required precisely the same exposure, there might be a possibility of utilising the actinometer in a scientific manner. But until outdoor practice is reduced to the level of reproducing what somebody described recently as "black letters on a white ground," I expect these gentlemen will have to go on "guessing," or, in other words, trusting—unconsciously, perhaps—to the wonderful amount of "rope" they have both in exposure and development.

I do not for a moment wish to dispute the value of even the simplest forms of actinometer—the simplest are as a rule the most accurate—for their proper purposes, the direct measurement of light. But they certainly do not meet the requirements of the landscape photographer, whose trouble lies rather in estimating the value of his subject and compromising the difficulties raised by its component parts than in ascertaining the precise strength of the light at the time of exposure. Variations of light occurring from day to day or from hour to hour are not in the least likely to operate disastrously even in the case of an operator tolerably careless in the matter of exposure, because they are more than swamped by the elastic nature of the sensitive plates and their treatment; but he who neglects to study

his subject and to see how he can best reconcile its antagonistic requirements is sure to come to grief. For his purpose the actinometer is of no more use than the tables of exposures published in our annuals and text-books; both the one and the other require using with brains.

Far better than any actinometer I consider the old dodge of carrying a couple of small pieces of coloured glass in the pocket, through which to view the landscape before exposing. Contrasts that do not strike the unaided eye unless trained to the purpose are brought out when the scene is scanned with, as it were, an artificial eye. Yellow glass brings into prominence the shadows of the picture, while blue emphasises the lights. This plan was never put forward as a scientific one nor as a method of accuracy; but used "with judgment" it is an aid to the practical worker which the actinometer can scarcely be.

ERNEST GRAHAM.

ECHOES FROM THE SOCIETIES.

MR. NEWTON is credited with a rather extraordinary statement, or so it seems to me, in the report of a meeting of the Society of Amateur Photographers of New York. I have always been under the impression that silver bromide was far more sensitive, relatively, to yellow light than the chloride, and that the latter was comparatively insensitive to yellow. But, according to Mr. Newton, "You take an orange coloured light, and it will act upon the chloride of silver about as quick as a white light. That is, any professional photographer who is printing on a day when the sky is clear and has a yellow light, will print his prints as quick as he would if it was a white light, and the action of that light on the bromide of silver would require at least double the time."

The idea that chloride of silver paper will print as quickly in an orange as in a white light is quite new to me, and I should be glad and not surprised to find that Mr. Newton is misreported. I think such must be the case, for he goes on to mix matters by saying that "when it begins to be late in the day . . . it is not a very difficult thing to take an instantaneous picture, but it will take a pretty long time to make a print on a piece of chloride of silver paper." Verily there is room for some explanation.

Then, again, it is curious to hear that Mr. Newton's rule is "to over expose always," though certainly the statement is qualified by the addendum, "that is, for a normal developer." But that can surely not be *over* exposure if a modification of the developer will make a negative. On the principle that "you cannot have too much of a good thing," an exposure cannot be too long if it effects its purpose satisfactorily. But here again Mr. Newton is somewhat indefinite, for he says, a little later, "I always have it a sure thing if I have got the right exposure." So I suppose the *right* exposure is *over exposure*.

At the same meeting Mr. Spaulding summed up the disputed question of the efficacy of the actinometer when employed with different lights in a very neat manner. He says in effect, "Suppose I have two weights of 300 pounds and 3000 pounds respectively to move across this room, and it takes me five minutes to move the lesser, how long will it take me to move the greater?" "Why, I could not move it at all," he replies, and goes on to point out that the comparison of a sunlight exposure upon chloride paper with an exposure to gaslight is just about as reasonable. I heard the very same idea expressed in a different manner some time ago. If two minutes' immersion in boiling water will coagulate the white of an egg, how long should it be immersed in water at 120°?—Fahrenheit, of course. The reply to this conundrum was, "As long as it would take to make an albumen print from a negative of ordinary density by gaslight."

The champions of the actinometer were hard to kill, for even after being told that the principle had been proved to be useless as well as "unscientific," one of them wished to know if there was anything scientific in the whole range of photography? This was rather hard on photography, but still harder, I think, the reply that "there is a good deal in photography that is scientific, but it has never been found out." Oh, ye scientific (?) writers! I thanked my stars last week that I did not belong to you, how much more so now!

But I think Mr. Ripley, who made the statement, must have meant to say that he had not "found it out." Whether he meant to say so

or not, he proved it, otherwise he would not have said that no two of the "best chemists of the world" would give "the same reason for the same result." Nor would he have expressed much doubt as to the reason why "collodion sensitised (*sic*) to-day" would give a different result in a month's time. In saying that that is "something nobody can tell" he is, however, perhaps speaking of himself again. "There is lots of science, but we don't understand it." Why not place himself under somebody who does, and go to the next meeting prepared?

The President was a trifle disingenuous in the way he fenced the question—"dodged" was the term applied by one of the members—as to whether anything could be done in development to make up for under exposure. The "gentleman in this room"—himself I presume—who maintained that "an under-exposed plate can be made as good as a plate that has been over exposed" neither answered the question nor spoke correctly. Excessive exposure can be held in check; absence of exposure cannot possibly be supplied chemically. A slightly under-exposed plate may be made passable, but never equal to a fully exposed one. A slightly (or very greatly for that matter) over-exposed plate may make a perfect negative. I use the term "over exposed" in relation to some definite form of development; within pretty wide bounds I don't believe in such a thing as over exposure if the development be made to suit. But under exposure places the plate beyond the reach of *any* form of development.

In answer to a question at the same meeting it was stated that Mr. Roche, of New York, had discovered a method which enabled him, after exposing a plate in the camera, to render it insensitive to any further impact of light without in any way injuring the image already formed or interfering with its subsequent development. This, if true, opens up quite a new vista in landscape work, and will deal a heavy blow at changing boxes and double slides. It recalls to my mind a Utopian dream of my very early photographic days, in which I imagined the possibility of taking out prepared plates in the insensitive state which, after placing in position in the camera, were to be sensitised by the injection of a puff of vapour of some sort, and after exposure desensitised in a similar manner. A single dark slide and an ordinary deal plate box, instead of the costly dark slides and changing boxes, formed no unimportant items in that early dream.

It seems that there is yet another French claimant for early photographic honours. M. Bayard is stated to have printed the first paper proof—a claim which I fancy will require verification. The process described is certainly a very old one, but I never remember to have previously seen it accredited to M. Bayard. I tried to work it with but scant success upwards of a quarter of a century ago, having come across it in some old receipt book.

I can comprehend the meaning of the pictures on "the 'Siamoise' plan" forming part of the late M. Bayard's exhibit before the French Photographic Society; they are, I presume, similar to those formerly called "binographs," or some such name, in this country. But I really cannot divine, in either English or French, what is meant by a person "fencing with his *sosie*." It would be better to describe such things in plain English I think.

In the report of another meeting of the same Society we are told of some new lenses that are said to be "joined together" with "*Canadian balm*." In English there exists no such substance, though that may be its French designation; but if it were necessary to mention the cementing medium at all it would have been preferable to describe it in an English journal under its English name, Canada balsam.

The keeping qualities of plates cropped up again for discussion at the Sheffield Society, and the opinion was expressed that a bromide plate would keep indefinitely if protected from damp and air. This I consider to be true and yet untrue, to assert too much and yet not to claim sufficient. A very important item is left out of the calculation, namely, the condition of the film to start with. If the emulsion has not been thoroughly washed to free it from soluble salts, or if it has contained at any period of its existence free silver, or supposing it to have been properly washed but not perfectly dried at first, it is hopeless to expect the plates to keep, however well packed and kept. A well-washed emulsion and well-dried film will, I believe, keep indefinitely if kept with only ordinary care; nay, more than

that, a well-washed pure bromide emulsion plate will suffer little even from the effects of subsequent damp, unless it be sufficiently severe and prolonged to result in the actual decomposition of the gelatine. Colonel Stuart Wortley has narrated in the account of his trip round the world how his plates—at least, those of certain brands—passed scatheless through the trying ordeal of three weeks of extremely rough and wet weather, when everything was in a state of incipient or well-developed mildew; and this, too, with salt water.

I had myself last winter a very remarkable example of the hardness of really good plates—good that is in the sense of the emulsion having been free from soluble matter, and of their superiority over others apparently equally good when put to the test. During one of the frosts a pipe burst in my dark room and a cupboard containing several different samples of plates was badly flooded, and, to make matters worse, the damage to the plates was not discovered for a considerable time; until, in fact, the plates had dried and become glued into solid blocks, some of them with paper between the films, others separated at the edges only. As a matter of curiosity, I took the trouble to separate some of the plates for the sake of testing them, and I must say I was surprised to find that two brands passed perfectly through the trial, being, with the exception of mechanical markings from the paper having been pressed into the soft films, as good as if the damp had never reached them. Other makes were, however, hopelessly ruined—I was going to say mentally and bodily—but what is equivalent, photographically and mechanically.

It is perhaps not strictly accurate to lay such a result at the door of the manufacturer's carelessness only, for the composition of the film may have something to do with the matter. Thus, a plate containing chloride of silver is far more liable to deterioration from atmospheric influences or damp than one consisting wholly of bromide, even though it may have been perfectly freed from soluble salts. An ammonia-made plate will also, *ceteris paribus*, usually prove inferior in this respect to one made by the boiling or digesting processes; unless, indeed, the decomposed gelatine has been removed by the "separator" or by one of the precipitation processes.

Iodide of silver, too, has been alleged to exercise a deleterious influence on the keeping qualities of a film, but I cannot say that I have ever been able myself to verify the charge. Indeed, one of the two brands of plates I have just mentioned as successfully resisting damp contains, I know, a large proportion of iodide. Still, I think there can, at any rate, be little doubt that plates whose films consist of pure silver bromide and dry gelatine only, may be considered to be permanent as the glass they are on, if properly kept. MONITOR.

STEREOSCOPIC PHOTOGRAPHY.

SOME of my friends say I am mad on stereoscopic work just now; well, perhaps that is so. Why did I ever give it up? Why did everybody else give it up about the same time? I can only give some account for *myself*—others must answer for *themselves*.

When I worked a stereoscopic camera many years ago (say twenty years ago), my instrument was not a *double distilled patent*, and in these days it would be considered a heavy and clumsy affair. Well, I admit it was heavy compared with cameras nowadays.

The size was $7\frac{1}{2} \times 4\frac{1}{2}$. I could use it for single views as well as for stereo work. But I became a great enthusiast in lantern matters, and wanted lantern slide negatives. It is true I could take two distinct pictures on each half of my $7\frac{1}{2} \times 4\frac{1}{2}$ plate—each picture then $4\frac{1}{2} \times 3\frac{3}{4}$; but having no opportunity to print by the camera, which required daylight, I could not very well reduce from the half of my plate to $2\frac{3}{4}$ or $2\frac{1}{2}$ picture on a $3\frac{1}{4}$ square glass, I was obliged to print by contact in the evening, therefore only a portion of my negative was utilised, and often the composition of the picture suffered in consequence. It may be said lines could have been drawn on the ground-glass (focussing screen), showing the size of the lantern picture, and the elements of the picture composed within those lines. Yes, I admit that sounds very well; but when we are out in the field we are very apt to compose the picture to fill the focussing glass, and the plate being larger, the camera and other apparatus bigger and heavier, &c., than then required, I parted with the whole kit, and went in for what I thought a more convenient arrangement for lantern work, namely, a quarter-plate camera, the best I could buy, and with that little camera I have taken hundreds of negatives, and it has travelled with me over thousands of miles.

To turn back to my old $7\frac{1}{2} \times 4\frac{1}{2}$ camera and its days, I should say that at that time we had to make our own dry plates, and for various reasons it was then considered necessary to take the negatives on a larger plate than the size of print required, thus giving some margin for defects from various causes. But this does not apply to-day. Gelatino-bromide plates and other advances do not render it important to have so much margin; in fact, a careful manipulator can now make sure of his negative being perfect to the edges.

After reading the Editor's chapters on *Stereoscopic Photography* in this year's ALMANAC—which I did with considerable interest—I turned to some of my old stereoscopic prints and transparencies a night or two afterwards, and whilst these pictures were still about some friends called to see me. They had not seen through a stereoscope for years, but, oh! how they did admire my pictures, and how pleased I was.

I routed up some old stereo negatives made on collodio-albumen and wet plates, and printed a few transparencies from these on gelatino-bromide plates, and what beautiful results I got! These transparencies would not do for the lantern at all; in fact, I will go so far as to say gelatino-bromide plates of *anybody's make* (commercial ones) are unsuited for making lantern slides; they are not clear enough or transparent enough without being hard, and if you do make them soft, they are veiled and flat, and therefore unsuited to the lantern. But this does not apply to the stereoscope. Some of the very finest stereoscopic transparencies are those fully exposed, even amounting to flatness (viewed as a monocular picture); and a little veiling in the sky and high lights, &c., is a decided improvement in many cases; or, in other words, were we to print a slide right for the lantern it would look hard and chalky—swoy—in the stereoscope. Then I say gelatino-bromide plates are more suitable for printing stereoscopic than lantern slides.

The question of going into stereoscopic work again had been occupying my mind some time before Mr. Pollitt and Mr. Abel Heywood, jun., came forward with communications on this subject one evening a few months ago at the Manchester Photographic Society. I took in all these gentlemen said, and examined their beautiful specimens, but I noticed everybody did not; some of the younger members had no interest in the subjects—thought it was too technical, and the results not showy enough for them—perhaps they went out and had a smoke! However, I made up my mind I was making a mistake in working a quarter-plate camera for lantern pictures alone, for with a plate two and a half inches larger, namely, $6\frac{3}{4} \times 3\frac{1}{4}$, I could make stereographs also, and if I did not want stereoscopic in some cases, I could still have my lantern pictures by putting two on one plate. (I don't mean tandem fashion, as one good friend of mine did the other day at Lyme Hall; he put two pictures on one plate, but could not very well separate them in the printing.)

Well, I made up my mind what to do, and *I have done it*: I have bought a stereoscopic camera with six double backs, the nicest little camera I have seen for a long time. There are plenty of them in the market cheap at present, and of all the cameras that were made fifteen or twenty years ago some of the stereoscopic size were the gems of workmanship, and will favourably compare for that, and even portability, with anything made to-day.

But I fear I am gabbling away without being practical. Everybody wants to read something practical nowadays; a fixed formula—put this and that together, and it will come out so and so; in fact, we shall soon have books on photography like our cookery books. But I will come to the practical by-and-by—if not this time, perhaps before long; but it's no use to tell how to produce results before we know the subject is acceptable.

Will stereoscopic work ever be popular again? I think it will, for more beautiful photographs than good stereoscopic transparencies are not to be seen, and there is no branch in photography more admirably suited to amateurs than stereoscopic and lantern work.

I have made a good few stereo slides during the last week or two, and exhibited them to many of my friends; the result seems healthy, for they were highly appreciated.

A dealer in plates, in Manchester, who keeps a small stock of stereo plates, and who only sells a dozen or two now and then, has been cleared out; he ordered more (the usual quantity); these, too, have all gone. He said to me the other day, "What's going on? There seems quite a run on stereoscopic plates just now. I am ordering by to-night's post a few gross, whereas I usually only order a few dozen."

I don't take all the credit for this, nor do I get any commission, you know; but if this class of photographs have taken a turn, and is going to be popular again, as it fairly deserves to be, then, I say, it will be some encouragement for others as well as myself to give a few practical notes on the subject.

The first thing to do is to make up your mind to go in for it; if

you cannot do that, and want assistance, send to G. W. Wilson & Co., Aberdeen, for a dozen stereoscopic transparencies and buy a stereoscope (you can spend pounds to worse advantage), and if these do not tempt you, pursue this subject no further—throw this paper aside; I shall write no more for you. But if you can make up your mind to go into stereo work, then get a binocular camera and a pair of lenses—from 8×5 to half-plate size will do—but for reasons already stated I prefer the $6\frac{3}{4} \times 3\frac{1}{4}$.

A single lens and sliding front board may be used, but this arrangement is not so good, especially when we have instantaneous work or subjects in which figures and life is introduced. A pair of lenses do not cost much, and single landscape lenses are the best and most useful, from four and a half to six inch focus. Rectilinear and symmetrical lenses are less necessary for stereo work.

Many of the existing cameras which are not provided with a moveable expanding partition can have one applied; but I regret to say most of the modern cameras are made with fronts and lens boards too narrow to admit of a pair of stereoscopic lenses, which should in most cases be placed so that their centres occupy the centres of divided plate, but in no case should the centres be less than three inches—three and a quarter inches would be better—and for many subjects even more would be advantageous.

In conversation with Mr. Harding Warner a short time ago, when I had the opportunity of inspecting some of his charming stereo slides and a new stereoscope, I think he said he used 10×8 plates for those pictures.

I have said they were beautiful pictures, but they were on paper, and I prefer glass transparencies as being more beautiful, almost as easy to make, and suitable to most amateurs, because they can be printed at night, and because we can apply combination photography to the stereoscope better with glass than paper.

Then I keep to the old size, because it is the standard size of all the commercial firms who produce such beautiful results in England, Scotland, and Paris. To alter the size would require a new size of stereoscope, and that would be almost as bad as writing music for a new keyboard of a piano. Then, again, we have them the right size for contact printing for the lantern. They are less expensive, the apparatus less expensive and more portable, and another important point is, that smaller lenses can be used, and these are usually quicker and more perfect instruments than larger ones, and when the slides are viewed by lenses in the stereoscope of the same focal length as those used to take the negatives, we get the effect of natural size. I am now having made, by a jeweller's casemaker, two box stereoscopes, with flanges fixed on, in which I can screw my Wil-onian landscape lenses, one for four and a half and the other for six inch focus.

I saw a beautiful looking camera the other day, 10×8 size. It was made so that half the plate could be used for single pictures and again divided, thus 10×8 pictures on one plate, two 8×5 pictures or four 5×4 pictures could be put on one plate, or two stereoscopic subjects. It would focus from about three inches to goodness knows what. It had arrangements for swinging, tilting, sliding, and revolving, in almost every conceivable direction, and as many brass levers and screws as could be crammed on; in fact, there was not much woodwork to be seen, it was all covered up with lacquered brasswork.

It had too many contrivances for my liking; no sensible or practical photographer would wish to make stereoscopic slides with a thing like that. For my own part, if I want 10×8 pictures I get a camera 10×8 , and if I want stereoscopic pictures I get a stereoscopic camera; the difference in size is too great to mix them up in one instrument.

I remember not long ago a young friend of mine going to learn mechanical drawing. He told his mamma it was necessary he should have a box of drawing instruments. So she took him to a swell optician's shop, and bought him a big rosewood nickel-bound box filled with instruments, *the very best they could buy*, and then came the colour box. As he did not know what tints he *would* require they bought nearly every colour in Windsor & Newton's list. My young friend had to engage a cab next morning to take his tackle to the office. The foreman draughtsman and most of the others engaged, who really *could* draw, had only about a twentieth part of the tackle, and perhaps a piece of washleather to serve for the nickel-bound polished rosewood box.

A good lot of this applies to many of the amateur photographers of to-day. I was very much amused with a friend of mine at a recent outdoor meeting of our Society. He had with him four new lenses, and having tried them all in succession, at last decided upon one he thought best. After making the necessary adjustments, the slide in the camera, and the shutter drawn, he took out a pocket-book and pencil. I watched him for some time, and at length I

thought he must be making a pencil sketch instead of photographing, so I went up to him to see what was going on. He had actually three printed tables and an actinometer at work; the multiplications and divisions he had gone through was astonishing. "What is it all for?" I inquired. "Why, to get at the correct exposure. Can you show me a better plan?" "Yes," I said; and I took the cap off and put it on again. He has told me since it was the only negative he got that day. I don't wonder at it. W. L. CHADWICK.

ON SYSTEMS OF NUMBERING PHOTOGRAPHIC LENSES AND DIAPHRAGMS.

[A Communication to the North London Photographic Society.]

MANY of my hearers will, I am afraid, consider that I have chosen a very dry and uninteresting subject; but when we remember that there are about half a dozen different systems in use amongst photographers it is surely time to weigh one with another, and, retaining the best, dispense with the others.

In deciding whether one system of numbering stops and lenses is better than another, we must keep in view the object or purpose of these numbers. That object is the *easy and accurate determination and comparison of exposures*; and this is, therefore, the test by which we should compare any one system with another.

Before going further, I must, for the benefit of beginners, clear the way by illustrating the meaning of one or two of the technical terms I shall have to use in the course of the evening.

Let us suppose for one moment that a candle is placed at a distance of nine inches from a lens, and that having focussed the image we find the distance between the latter and the centre of the lens to be—as it might be—eighteen inches, then if the candle were moved three inches further from the lens we should find that the distance between the lens and the image, when the latter is in focus, would be reduced to twelve inches. If, again, the object we are photographing is still further off, say eighteen inches, the distance between lens and focussed image will be only nine inches; and if, finally, we turn our camera towards some object a long way off, the distance referred to will be reduced to practically six inches.

These distances of—in the last case—a trifle over six inches, and in the previous cases of nine, twelve, and eighteen inches, I shall call *image foci*, so that when I speak of image focus you will remember that I refer to the distance between the optical centre of the lens, or say the place where the stops are inserted, and the focussed image formed by the lens.

You will have noticed, from the illustrations I have given, the general principle that the greater the distance of the object from the lens the less will be the distance of the focussed image from the same point; but you will find that, gradually reducing the distance between ground-glass and lens, you will at length come to a point beyond which it will be useless to move the ground-glass screen, however far off the object may be, because, if you do move it beyond this point you will only find a blurred image of the object. The distance between the centre of your lens and the ground-glass when the latter is at this point is the principal focus, better known to some of you as the equivalent focus of the lens.

You will notice that while the image focus is always changing, the principal focus, or, more correctly, principal focal length, is constant. It depends upon the construction of the lens, and will not vary unless the lens itself is altered.

I will now explain in a practical manner the two rules which assist us in judging the necessary exposure under different conditions of lens and stop.

The first is that the exposure required will vary in the same proportion as the square of the image focus. For example, suppose that one second is the correct exposure under certain conditions. Now if all these conditions remain, except that the working focus is doubled, then the exposure required will be, *not double* the previous exposure, but 2^2 , that is, four times.

I can best show the truth of this rule with the help of these models, which I have roughly prepared for the purpose. This model (a small model in the shape of a pyramid) represents the direction of rays of light passing through a small aperture, the back of the model representing the layer of light intercepted by an opaque screen.

If you move this screen (the base of the pyramid) twice as far from the point of light as it is at present, the rays, continuing to diverge, will cover a much larger surface, in fact, you will find, on measuring, that the surface now covered is just four times as large as that previously covered; you have just the same amount of light, but it is spread over an area four times as large. The light, therefore, at the surface of *this* screen (the base of the second model—the distance

from apex to base in this case being twice that in the former case) is only one-fourth as concentrated, or, in other words, one-fourth as intense as at the surface of the nearer screen. This being so, the exposure required in order to obtain the same result on a photographic plate at *this* (second) distance from the diaphragm will be four, that is, 2^2 times that required in the former case. Beginners might easily fall into the error of supposing that this rule depends upon the size of the plate, but you will observe that nothing has been said about the size of the plate, but only of the distance of the plate from the diaphragm.

In the same way if I remove the screen to three times its first distance, it will be seen that the light—spread as it is over nine times the first area—is only one-ninth as intense, and a plate will therefore require nine (that is, 3^2) times the first exposure.

If, then, we call the first distance one, and the exposure required one second, the second distance will be two, and the exposure required will be 2^2 , that is, four seconds, and the third distance will be three and the exposure 3^2 , that is, nine seconds, or, in other words, the exposure required varies as the square of the image focus.

The second law relative to exposure is that the exposure required varies inversely as the area of the diaphragm, or, what amounts to the same thing, the square of the diameter of the diaphragm. For example: If under certain conditions the correct exposure is one second, and these conditions are altered only as regards the diaphragm by putting in one of one-fourth of the area of the previous one, then you must give four times as long an exposure. If, again, you substitute a diaphragm twice as large, that is, having twice the area of the first one, you must give half the exposure.

I might explain this by saying that as the aperture is twice as large you will, of course, get twice as much light through it, and consequently will only need to give half the exposure. But as such an explanation would give a beginner no idea of the true reason I will endeavour to explain it.

Rays of light are, as you may know from daily experience, reflected or emitted by materials in straight lines, and in all directions. Here is a sketch showing a side view of a diaphragm with the rays reflected from, say, a small stone. If your lens is turned in the direction of this stone some of the rays will pass through the diaphragm and through the lens, and *being bent out of their course* by the lens, will form on the ground-glass a luminous point corresponding with the stone.

Now you will see at once that if I substitute for this diaphragm one having twice the area, *twice as many rays*—that is, these outside rays which were before prevented from passing to the ground-glass by the metal disc—will now be able to pass through the diaphragm and lens to the ground-glass, where, in consequence of the refracting influence of the lens, they form an image exactly overlapping the previous image. The image is now twice as bright as before and will therefore require only half the exposure. Of course the same explanation applies to *every point* on the ground-glass, and as the *whole image* is nothing but a *number of luminous points*, it applies to the whole image. If we substitute a diaphragm having three times the area of the first one, three times as many rays will be able to pass through to the ground-glass, thus illuminating the image three times as much and requiring therefore only one-third the exposure.

I have now only one other preliminary reference to make and that is with regard to the standard numbers of the Photographic Society; these numbers are based upon a unit which has been found by a committee of the Photographic Society of Great Britain to be the best unit for practical purposes, and as uniformity in matters of this kind is of great value we ought to recognise these numbers and make more use of them than we have hitherto done. Without uniformity—that is, without some recognised standard—there can be no comparison of exposures between photographers.

I am this evening going to speak of five different systems. If any two of these should be found in practice equally good, but one recognises the standard numbers and the other does not, then we must give the preference to the former.

The first of the five methods just mentioned is the *f* system.

I was out with this Society a few days ago, and, standing near two of our members in a wood, overheard the following:—

"I say, Doctor, what exposure ought I to give for this?"

"Well," says the Doctor, "I'm going to give fifteen seconds for f_8 , and I think that's about right."

After considering this reply for half a minute or so the questioner asked how he could find out what exposure he ought to give for f_{16} —the aperture he was using. In reply to which the Doctor told him to divide twenty-two by thirteen, square the quotient and multiply by fifteen, and the number thus found would be the required exposure in seconds.

I could not resist remarking to the Doctor that if we could not get more direct answers than that in our everyday work the demand for calculating machines would be on the increase. However, the Doctor was not to blame, for he did the best that could be done with the system. Yet nearly everyone expresses the rapidity of his lenses by means of this system—the beginner sometimes because his stops are numbered according to this system and sometimes because he knows no other plan; the professional partly from habit and partly because, as he very seldom *calculates* his exposures, it does matter to him how his stops are numbered. Besides the objection to the *f* system which I have illustrated there are three or four others, but as they constitute the whole of the objections to the next system I shall speak of I will not discuss them here.

As I illustrated the working of the *f* system so I will now illustrate the uniform system. The Doctor has been asked what exposure is required for U.S. No. 22, to which he replies that he intends to give fifteen seconds for U.S. No. 13. "To find the exposure you ought to give," adds the Doctor, "divide twenty-two by thirteen, and multiply by fifteen; the number thus found will be the required exposure in seconds." There is, however, no need for this amount of calculation. If I wanted to know the value of twenty-two yards of cloth I should expect to be told the price *per yard*, not the price for thirteen yards; and we all know that there can be no simpler way of quoting prices for commercial purposes than this. Yet it does not seem to have occurred to photographers that this simplicity can be applied to their own work—that, as drapers always quote the price of cloth per yard, having in view *one idea* only, that is the quality of the cloth, so it is possible for photographers to quote the exposure per unit, that is, in this case per standard number, having also only one idea in view, namely, the actinic power of the light reflected from their object. If this plan of quoting exposures per standard number were adopted we should have in the uniform system the simplest plan that could be devised.

The *simplest*, certainly, but not the most accurate. It answers our purpose to put up with a certain amount of inaccuracy for the sake of simplicity, but in some cases the U.S. numbers are so inaccurate as to be quite useless.

You will readily see that these numbers are not really comparative exposure numbers, for the latter, as you know, vary with the square of the image focus, while the U.S. numbers depend on the square of the principal focus. In taking landscape and distant views there is only a very slight difference between the latter and the image focus, so that in these cases the U.S. number may be used as the comparative exposure number. But for indoor work—portraiture, copying, or enlarging—where the image focus varies very considerably from the principal focus, the U.S. numbers are *too* inaccurate. In these cases, therefore, the photographer must find some other system.

Again, a person working with a set of combination lenses cannot use this method; for what will be U.S. No. 30 with one combination will be U.S. No. 50 with another. Diaphragms are sometimes sold apart from lenses, such for instance as those sold with Grimstone's instantaneous shutter. These cannot be numbered by manufacturers in accordance with either the *f* system or the U.S. system.

All these objections may be removed by eliminating from the U.S. number that part of it which depends on the principal focus. The formula for finding the U.S. numbers is $P^2 \times \frac{1}{16a^2} (= \frac{P^2}{16a^2})$, and that for finding comparative exposure numbers is $m^2 \times \frac{1}{16a^2} (= \frac{m^2}{16a^2})$. (P = principal focus, a = the aperture of the diaphragm, and m = the image focus.)

Following the suggestion I have just made, our stops will be numbered in accordance with the formula $\frac{1}{16a^2}$, so that to find the comparative exposure numbers we must multiply these stop numbers by m^2 . On putting this into practice, however, we shall find that these stop numbers will be rather too high for easy use. This difficulty, however, may be overcome by slightly altering our formulæ; thus $\frac{m^2}{4 \times \frac{1}{16a^2}} (= \frac{m^2}{\frac{1}{4a^2}})$, though as you see we do not alter the result.

While these formulæ are on the board I may as well show you what sort of numbers they will give. Taking the usual run of stops to be from one-twelfth of an inch in diameter to one and a half inches, and the image focus to extend from four inches to twelve inches the numbers will be, for the lenses from four to thirty-six, and for the diaphragms from thirty-six to one-ninth.

These numbers are not too high to deal with easily. This one ($\frac{1}{4a^2}$) you will have stamped on your diaphragms; but the other you cannot have stamped on your lens for it is constantly altering, and it would be absurd to suggest the practice of measuring the distance between ground-glass and lens and making use of the formula $\frac{m^2}{4}$. The simplest way of getting over this difficulty is certainly by

means of a measure such as this one which I will presently pass round. It is marked in such a way that on placing one end against the centre of your lens you will see the value of $\frac{m^2}{4}$ on the tape opposite to the ground-glass.

This system is technically perfect and may be applied in every case; a stop marked in accordance with it is correctly numbered whether used with a six-inch combination or a nine-inch, whether you are doing landscape work, or enlarging, or copying. I would suggest that all stops be marked in accordance with this formula ($\frac{1}{4a^2}$) as well as with the U.S. number, so that in taking distant views the photographer may, by using the U.S. numbers, avoid all calculation, and where circumstances do not permit of his using U.S. numbers, then he can use the method which I now recommend and which I think will be best described as the comparative exposure system.

I have now to speak of the area system. The formula for finding the stop number is $\frac{(64a)^2}{10}$, and for the lens number $\frac{(4n)^2}{10}$. This system is not to be condemned on account of the complicated formulæ upon which the numbers depend; but we shall not find the *numbers themselves* everything that could be desired. Taking the same range of stops and lenses as before, you will find that under the area system the stop numbers will run from 2 up to 920, and the lens numbers from 25 to 230. In presence of such high numbers I do not think it necessary to make any further remarks on this system—we are literally overpowered by numbers.

I will draw your attention to a formula, given in connection with this system, for finding the area numbers of any combination when you know the numbers of the separate lenses.

The formula is $\frac{x+y}{8}$, x and y being the area numbers of the separate lenses. This formula is remarkable for its simplicity and its inaccuracy. Take a combination composed of a five-inch and a nine-inch lens—the area number for the combination according to the formula given would be 21, but according to the true formula 16. The fact is, the formula given is true in one case only, and that is when the two lenses are of equal focal lengths, and this is a case which you never find in practice, for no combination set has two lenses of the same focus.

Another objection to this system is that it takes Standard No. 16 as its unit and not Standard No. 1. And as the lens number depends on the principal focus, it is, in common with the *f* system and the uniform system, inaccurate when the object is at a less distance from the camera than twenty times the focal length of the lens.

Stops are sometimes numbered 1, 2, 4, 6, or, as the case may be, in accordance with the comparative exposure required, calling the largest diaphragm No. 1; but as the size of the largest aperture will vary in different sets of stops this method depends upon variable units, thus preventing any comparison between one photographer and another, besides rendering difficult the use of tables of exposure such as Mr. Burton's or Mr. Howard Farmer's. This plan is therefore practically useless.

I have now been through my list of systems, and have selected as best the joint use of the U.S. and the comparative exposure systems. It will be useless to mark stops already cut with the formula $\frac{1}{4a^2}$, because the numbers would probably be found to be decimal numbers or numbers too clumsy for easy use; but, of course, diaphragms may be cut so as to give the simplest numbers possible. To show this clearly, as well as to show how the union of systems which I have recommended would work, I have prepared a table similar to No. 3 table in Burton's *Modern Photography*. In a slightly extended form this table would be very useful to those manufacturers who might wish to number their stops in accordance with the plan here suggested. The second column shows the exact diameters of all the stops that would be necessary from one-thirteenth of an inch to three inches, the first column shows the Nos. of the drills to be used for cutting these stops, and the third column gives the comparative exposure stop number. This number would be stamped on the diaphragm and would be correct whatever lens it was used with. The other columns show the U.S. numbers in just the same way as in Mr. Burton's table.

Suppose that a person wants a set of six stops for a ten-inch focus lens, the full aperture of which is not quite one and a half inches. He will find in the second column the diameter 1.4 as the next stop smaller than one and a half inches; against this diameter he will find on the one side the drill to be used, and on the other one of the numbers which will be stamped on the diaphragm; further along, under the column headed focal length 10 is the U.S. number, which *also* will be stamped on the diaphragm. Then looking up the same column he will see the U.S. numbers ranging up to 400 for various sized stops; he finds against No. 400 that the diameter of this stop would be

one-eighth inch, but as he does not want so small a stop he makes use of the next row—No. 9 drill, Comparative Exposure Stop No. 12, U.S. No. 316. Then having decided upon the largest and smallest stops, he can choose intermediate ones from the list at his pleasure and in a similar manner.

The comparative exposure stop numbers are here preceded by either a multiplication or a division sign; this prevents the possibility of any one forgetting how these numbers are to be applied to the number on the tape measure, and in the case of the numbers preceded by the division sign it is simpler to write $\div 6$ than $\frac{1}{6}$. It will be seen that the U.S. numbers are in most cases rather high and awkward numbers to deal with, but there is no necessity in practice for extreme accuracy. It will be quite near enough if instead of numbering a stop $\frac{1}{11}$ it is numbered 7; $\frac{1}{68}$ can be numbered 10, and so on. But the fact of these numbers being odd and high numbers is not really of very much consequence, for you do not have to go through a series of calculations with them in order to arrive at the requisite exposure as you do in the *f* system. Having in your mind Mr. Burton's or Mr. Howard Farmer's list of exposures for Standard No. 1, you have merely to multiply these by the U.S. number.

Here is a table of area system numbers, taking the same lenses and stops as in the previous table. The top row consists of the principal foci, and immediately beneath these are the lens numbers; in the first column are the drill numbers, and against them the stop numbers. It will be seen that there is but little to choose between this table and the other as regards the character of the numbers, but in the area system you have two numbers to deal with—the one having to be divided by the other. In the uniform system you have the quotients worked out and stamped on your stops, while in the area system you have to work them out yourselves.

In conclusion, I strongly recommend every one in speaking of exposure required to give the exposure per unit, that is, per standard No. 1 ($\frac{1}{4}$).

I would also advise those who have stops marked according to the *f* system to renumber them in accordance with the uniform system. This is done by dividing the *f* number by four and squaring the result. For example, take $\frac{1}{4}$ —24 divided by 4 = 6, $6^2 = 36$, and this is the U.S. number.

O. SMITH.

PHOTOGRAPHIC PAPERS AND PAPER MAKERS.

III.

We have seen that the good typical photographic paper used by Captain Pizzighelli and Baron Hubl, is that known to the trade as "ivory vellum wave," bought from the mills when but half sized, the final sizing of gelatine or starch being given to it by the photographers. When such paper is finished at the mills to be sold as writing-paper, a final sizing with gelatine and alum is also given to it, but the gelatine may not always be of the hard description which a photographer would be wise to employ; however that may be, the fact is now elucidated that when a photographer wishes to try experiments in printing processes upon plain paper, and at his own risk ventures to use such papers as he can buy at stationers' shops, that which is most likely to answer is "the best cream or ivory vellum wave writing-paper," with or without a resinous foundation. Sometimes it answers well for certain plain paper processes; its chief defect is that it too readily absorbs aqueous liquids. Sometimes it may contain injurious impurities as "fillings;" sometimes also traces of thiosulphate of soda are found in it, in which case it is useless for silver processes, but manufacturers can obviate this by substituting sulphite of soda to neutralise the chlorine after the bleaching of the pulp, taking care that the sulphite is used in moderation and not in excess.

Real cream or ivory vellum wave papers are not kept at many stationers' shops, and something else is sometimes tendered as such in their place, the point not being thought by the vendor to be of importance.

All papers used in photography should be made of cotton fibre; the cellulose from wood, which is now turned out of such good quality that experts often have difficulty in telling whether it enters into the composition of a paper, yellows with age and under the influence of certain chemicals more rapidly than does cotton cellulose. The paper made of rags which have never been used, and which are new and clean, is strong. It makes a harsh noise when cut with a knife, and offers more resistance than other papers to the passage of the blade; in photographic baths it is more tenacious and less liable to tear than other papers, which are qualities of no small value. Great harshness is not altogether preferred when making writing papers, a mixture of pulp from cleansed old rags being usually mixed with pulp from new rags, to impart additional flexibility.

Captain Pizzighelli and Baron Hubl state that the paper they

use, and cover themselves with a special gelatine or starch sizing, comes from the mills half resin sized. The resin is probably dissolved in carbonate of soda, and then mixed in with the pulp before the latter flows upon the machine. Should any English makers begin to meet the demand for photographic papers, this part of the operation demands their critical attention. Common rosin makes anything but a durable varnish, and something more stable might be substituted for it in half sizing papers in the manner stated. Rosin is furthermore to be viewed with suspicion from its manner of preparation; it is the residue left in the retorts or pots after distilling or boiling off the turpentine, and who is to say how much iron rust and other impurities get into it from the use of unclean iron vessels? Possibly some of those iron spots which have troubled photographic paper makers have not come from carefully cleaned machinery, but from rosin boiled down in the backwoods. Evidently the alkaline sizing material should be carefully filtered more than once before use. Some papers are said to yield under sulphur tests evidence of the general presence of iron; may not some of the resinous acids possibly take up traces of oxide of iron from retorts in which the turpentine is distilled off? Shellac is a resin of recognised good character for photographic purposes. The New Zealand cowrie gum is cheaper, and has some of the properties of copal. Both shellac and cowrie gum are soluble in alkaline liquids, so to these two resins attention might be given when making a partly resin-sized paper for photographic purposes. Writing papers of the highest quality contain no resin of any kind.

Recently I had the pleasure of going over the works of Messrs. Joynson & Son, St. Mary Cray, Kent, which firm has long been noted in this country for the manufacture of high class writing papers.

Into the operations of making the pulp from linen rags, and then bleaching it, it is not now necessary to enter, but it may be mentioned that the men in the bleaching rooms, in which there is always a feeble smell of chlorine, seem to be more protected against some classes of disease than are others not so employed. The only objectionable physiological effect of the traces of chlorine seems to be that it in time somewhat yellows the balls of the eyes of the workers.

The pulp having been placed in a feeding trough, is evenly discharged upon the fine "wire cloth" endless band of the paper making machine, and this shallow pool of emulsion is thereby carried on to the first pair of rollers. Before it reaches them the "watermark" is printed from a single roller carrying the design in relief. This design is distorted as carved upon the roller, because the paper is subsequently elongated more in one direction than the other, and this second distortion rectifies the printed impression of the first one. The watermark is usually a nuisance in plain paper photographic processes. Often, especially in landscapes, it comes upon such a part of the picture as to do no harm; it is most objectionable when it comes across the face in a large head. When the prints are wet, the watermark often spoils the appearance of the picture when it will not do so after drying. There is a difficulty, especially to non-experts, in telling which is the right and which is the wrong side of cream vellum wave writing papers, and a photograph taken upon the wrong side will often be a bad one, for all the natural roughness due to wire marks reappears after passing through the bath and drying. The watermark is no guide, except with the particular batch in use, as to the right and wrong side of the sheet, for sometimes it is printed to read right from one side and at other times from the other side. Hence, in a photographic paper, a very small watermark at each corner of the sheet, and consisting of the word "back," would be useful.

The first pair of rollers which receives the pulp administers to it very gentle pressure, after which the pulp adheres somewhat to the lower roller, but is drawn from it by the second pair of rollers between which it has to pass. This pulling of the soft pulp from the roller already mentioned causes many of the fibres to arrange themselves in the direction of the line of tension, and this is the cause of that great trouble to photographers of wetted papers elongating more in one direction than they do in another. Their breaking strain varies also in the two directions: a piece cut out of a sheet of paper in one direction will sometimes bear fifty per cent. more weight than a piece cut at right angles to that direction.

In the course of its passage along the machine, the paper enters the sizing bath. The gelatine in this is made at Messrs. Joynson's works, by boiling down the skins on the premises, skimming off the oil, mixing in some alum, and using it at once. On the machine it is kept at a suitable temperature. In this sizing bath we come to a point at which in photography two roads branch off. For some photographic processes a sizing of gelatine is the best, or, at least, is not objectionable; for others, and perhaps the majority, a sizing of pure starch, in the shape of arrowroot, is best. Certain salts of the noble metals tend to throw down a precipitate when they come into contact with gelatine, and this precipitate may be insoluble in the

fixing liquids, in which case we have photographs likely to darken in the whites by lapse of time, or by the presence of impurities in the atmosphere. Recently I published that a discrepancy existed between the statements of Mr. W. Willis and Captain Pizzighelli as to the relative values of gelatinous and starch sizings in the platinotype process; since then Dr. Vogel has published in the *Photographische Mittheilungen* that platinum prints upon a starch substratum discolour less in the whites under the action of sulphuretted hydrogen than they do upon a gelatine sizing, so that by Dr. Vogel the statements of Mr. Willis are fully supported.

On some of the machines at Messrs. Joynson's works, the paper, after being sized, passes over dozens of light wire-work rollers, in the centre of which are revolving fans, so that by the time it has slowly reached the end of the series it has been dried at nearly the normal temperature of the air, the machine rooms being but moderately warm. The weight of water thus carried off by the air of the rooms in the course of a day is considerable. Finally, the paper is cut into large sizes, and delivered cut and dried at one end of the machine, which at the other end it had entered in the state of pulp.

Fine writing papers are pressed in small sizes, by placing each piece separately between two polished sheets of copper or brass, the whole being then passed between steel rollers driven by steam. This is found to be the best way to get a fine surface.

W. H. HARRISON.

Our Editorial Table.

THE OPTIMUS EURYSCOPE.

London: Perken, Son, & Rayment.

WHILE we greatly dislike to be dragged into anything that bears the semblance of a disagreement among opticians, yet do we see no way of escape from that position as it at present exists between two large, responsible, and highly respectable firms, one at home and the other abroad.

The term "Eurycope" is the bone of contention at present between Messrs. Voigtlander on the one hand and Messrs. Perken, Son, & Rayment on the other. As will presently be seen we hold that it belongs by right of initiation to neither of these firms. But being public property it is open to be accompanied by a qualifying adjective. Why we say that the term "Eurycope" is public property is this: Several years anterior to its adoption by either of the two firms mentioned it was in common use in an optical establishment in the Strand, that of Mr. John Browning, who volunteers proof thereof by printed catalogues, ledger entries, and other means. This we have ascertained as a fact beyond doubt.

Assuming that the term "Eurycope" may now be held, in photography, to indicate a lens of the Steinheil type in which the angular aperture exceeds $\frac{1}{2}$, any distinction between the productions of two or more makers must be indicated by the qualification of the manufacturer's name or his trade mark, such as "The Voigtlander Eurycope," "The Optimus Eurycope," and so forth.

We are not so conversant with the Greek language as to be able to give the exact phase of signification of the word "Eurycope," but on the assumption that it is connected with seeing widely or expansively, or taking in a considerable field of the subject under consideration, we scarcely think it to be the best term to convey a precise idea of the peculiarity sought to be embodied, which should, from its increased angular aperture be that of a "bright light;" hence the term *leukoscope* as applied to a certain lens of American manufacture.

We have said before, and it is scarcely worth saying again, that the lens, the name of which is now in dispute, was invented both in its general form and the materials out of which it is made, by the late M. Steinheil, of Munich. In form it is a doublet, each lens of which is a cemented compound composed of a concavo-convex (convex side out) to which is cemented a meniscus, or convexo-concave. The former is a diminishing lens, and is formed of dense flint; the latter is a magnifier and is composed also of flint glass, but having a lower index of dispersion than the other. In fact, as regards their relationship to each other they are analogous to ordinary optical flint and crown glass. We have nothing here to say regarding the patent obtained in 1877 by Messrs. Voigtlander for their modification of the Steinheil lens, having said all that was necessary as to this at the period when the specification was published.

We now turn to the "Optimus Rapid Eurycope," manufactured by the firm of Perken, Son, & Rayment, Hatton Garden, an example of which is on a camera on our editorial table. With its full aperture of one and three-quarter inches (its equivalent focus being eleven inches) it defines with extreme brilliance, and when used with a stop

it easily covers a 10 x 8 plate to the corners, which is larger than that engraved on the mount as its possibility. Working as it does with such a large aperture ($\frac{1}{4}$ approx.) it serves as a portrait and group lens as well as a landscape and copying objective. There is no doubt of its proving a most useful lens. Altogether, by whatever name it may now or henceforth be known, this "rose smells sweet."

VIEWS IN AMERICA.

By JOHN REID, Paterson, N.J.

WE have this summer been favoured by visits from an unusual number of gentlemen, and ladies too, from America, connected either as amateurs or professionals with photography. It cannot be too well known that we are always glad to see visitors from a distance, and to place at their disposal all the resources of our offices, and also that of a commodious dark room in which to develop or change their plates.

Among our latest visitors was Mr. Reid, the well-known photographer of the large manufacturing city of Paterson, New Jersey, who has left with us several examples of his work. These are all taken direct, in contradistinction to being enlargements, a fact necessary to be mentioned when we say that some of them measure close on thirty inches. The largest pictures, which represent engineering productions, were, Mr. Reid informed us, taken by a single lens of fifty-two inches focus, the front element of a large portrait combination.

In large groups Mr. Reid is eminently successful, to judge by the Caledonian Society of Paterson; while his *Passaic Falls*; view of *Union-square, New York*; the palatial *Residence of C. Vanderbilt*; *Trinity Church, N.Y.*; *Groups of Curlers*; *Statue of Liberty*; and the intensely funny scenes caught on the beach at Coney Island, equally attest the skill of the artist in other directions.

THE MANCHESTER EXHIBITION.

V.

THERE are so many high-class photographers in the Manchester Photographic Society, that it would have proved no difficult matter for them alone to have provided material for a photographic exhibition worthy of the period without external aid.

When we examined a view, *Near Odde, Norway*, by Abel Heywood, jun., we made a note, "This ought to have been hung lower; it would well bear it." But Mr. Heywood has others to which this hint does not apply, amongst them being a *View on Ribble*, possessing fine atmosphere, and a *View in Patterdale*. In addition to four fine views of and in Hardwick Hall, J. H. Greatorex has a nice *View of Lynmouth*, and in another frame a series of views of this favourite North Devon resort, with similar views of other localities.

The portrait of the Lord Bishop of Chester, by Rev. H. V. Macdonald, is a noble piece of work. The face of the portrait of Thomas H. Nevill is all that can be desired, but from the point of view occupied by us during examination it seemed as if a little more detail in the coat would have enhanced it. Would this have arisen from its being a bromide enlargement? The *Yachts on Windermere*, by J. W. Kenworthy, are good; but the "*Isaac Walton*" Inn, *Dovedale*, by this artist, would have been improved had a little bit been trimmed off the foreground. This applies also to one of Mr. Hutchinson's otherwise excellent views. Quite a number of charming pictures are exhibited by C. H. Coote and also by W. G. Coote, the latter artist having succeeded well in the difficult feat of getting a lady admirably posed in the foreground of one of his views. Of several excellent subjects contributed by E. Leader Williams we must congratulate him upon having "spotted" a most capital one in his *Cottage in Worcestershire*, of which he has made a very attractive picture.

We expected to see a plethora of the visit lately paid to America by the Honorary Secretary, W. I. Chadwick, nor were we disappointed. In most, if not in all cases, his exhibits are enlargements from small negatives.

Mr. Chadwick acted most sensibly in preferring a small to a large camera as his *compagnon de voyage*. Concerning this journey we remember him writing to us, "I used only quarter-plates on my American trip. I made 350 good negatives; developed twenty-four in America, and the others after I returned to England; and the twenty-four developed on the spot are about the worst of the lot. I shall never develop again from home." We have inserted this as a piece of practical information to many who, about to go abroad, are undecided as to the propriety of developing their negatives *en route*, or delaying this operation till they return.

But in addition to many highly interesting American views, in which Niagara is well cared for, Mr. Chadwick contributes also a nice series of 5 x 4 pictures, *Holiday Reminiscences in the Isle of Man*.

PATENTS COMPLETED.

IMPROVEMENTS IN BOXES FOR HOLDING PHOTOGRAPHIC PLATES.

No. 11,615. SAMUEL DREW ARUNDEL, Penn-street Works, Hoxton, Middlesex.—*September 13, 1886.*

My invention relates to an improvement upon the boxes at present in use in which photographic dry plates are packed by the manufacturers, its object being to facilitate the removal of the plates, which with the grooved boxes at present in use is somewhat difficult. The boxes are usually made of cardboard, strawboard, or other light material, and are formed with a draw-off cover of considerable depth, in order that the light shall be prevented from getting to the plates, the inside ends having grooves of corrugated paper, or tin, either plain or paper covered, or cut wooden grooves, in which the plates are held. My invention consists in forming on such a box at both ends a hinged flap above the level of the grooves (which would not be carried quite up to the top of the box), and which flap may be readily bent back, exposing the edges of the plates, so that they may be conveniently removed by the fingers without the necessity of reversing the box and dropping all the plates forward before one can be picked out.

The hinge or flap may be formed in many different ways, but the most convenient I have found is to score the ends across at a distance of about half an inch from the top, so that the card or strawboard may be bent outwards when a plate is to be removed.

In this way, when the cover is on, if any light were to find its way underneath it at the ends, it would be deflected up into the cover, and would not pass over the top of the plates, so that the box remains fully as light-tight as the ordinary one, while, when the original purpose of the box is served, the flap may be torn off, and when used for storing negatives the same advantage will be experienced.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.
On Thursday night, August 4, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. J. B. B. Wellington presided.

The HON. SECRETARY read the following letter from Professor Stebbing:—

"DEAR SIR,—In answer to your letter of the 27th, I have the honour to inform you that on the 21st of March, 1887, the youthful Photographic Society of Douai sent in a proposition to the Commission of the forthcoming Universal Exhibition of 1889, in which they emitted a desire that a Photographic Congress should be held. This proposition was favourably received not only by the Commission but also by the Committee of the Département du Nord.

"This idea has not been followed up as perhaps we might have hoped. The President of the Société Photographique du Nord writes me that they have not up to the present issued any circulars; their rôle has been simply to indicate the questions which, in their opinion, ought to be brought before the Congress. The President adds, 'It appears to me that it is the duty of the Special Committee of Class 12 (Photography) to compose a programme of such a Congress, to invite professional photographers, amateurs, and manufacturers of every country.'

"This is, Dear Sir, the only information I can give you very honourable Association, to whom, as well as to yourself, I forward on my best compliments.—Prof. E. STEBBING."

It was resolved to telegraph from the Association a message of congratulation to the American National Convention of Photographers, now sitting at Chicago.

Mr. W. T. WILKINSON, of Cambridge, said that the air brush could be utilised in photo-mechanical work. He charged it with a solution of bitumen and caused it to discharge fine spray over a polished copper plate; with a little practice a kind of aquatint in appearance could be evenly distributed over the surface. A carbon print from a transparency was then squeezed down upon the plate and developed thereupon, after which it was put in perchloride of iron to etch the plate where not protected by the print and the minute particles of bitumen; the protection afforded by the latter gave the necessary grain; the plate was next washed, put in the press, and proofs pulled. The distance of the brush from the plate when distributing the spray influences the character

of the proofs. The shadows of the print are given by the depressions in the plate. After the carbon print is developed upon the plate it is hardened by alum. The plate must be etched directly the print is finished, and must not meanwhile be allowed to dry. The principle of the process is very old, and was used by Fox Talbot.

Mr. A. L. HENDERSON asked if Mr. Wilkinson would exhibit some plates and the results.

Mr. WILKINSON, for some reasons he stated, was unable to give a promise to that effect.

Mr. A. COWAN asked if good depth in the shadows were obtained or if the prints were flat-looking.

Mr. WILKINSON replied that he obtained good depth in the shadows.

Mr. HENDERSON supposed that sandpaper put over a copper plate coated with bitumen and run through the press would give a grain.

Mr. WILKINSON said that the gradual action of the perchloride of iron could be seen, and that the etching had to be stopped just when it began to touch the lights; he used a half saturated solution. The inking of colotype plates is difficult; the ink bought in the shops is usually too hard, and should be lowered with lard; it takes from twenty minutes to half an hour to properly charge the roller for colotype work, and then the observer would think that there was almost no ink at all upon the slab; beginners usually fail by applying too much ink. Very long exposures are supposed to be necessary in the direct bitumen process, but if the bitumen is properly prepared with ether printing upon it is as rapid as upon albumenised paper, and it will give as perfect half tones as will silver.

Mr. HENDERSON remarked that the Chairman had found out a way of preparing plates, by which it was simply impossible to make plates frill if the attempt were made to do so.

The CHAIRMAN stated that he did this by soaking the cleaned plates for a few minutes in a solution of chrome alum and water, the particular strength of which was not of much importance. He then rubbed them with a clean rag under water running from a tap, and afterwards stood them up to dry.

Mr. W. H. HARRISON thought that the study of the properties of thin films upon previously cleaned solid surfaces would be useful in photography. Bunsen had tried experiments as to the power of adhesion of such films, and calculated that their pressure to the square inch was enormous.

Mr. COWAN said that one way of obtaining a chemically clean surface to glass was to coat it after ordinary cleaning with a solution of gutta-percha, and allow the same to dry. When dry the film was stripped off and left an absolutely clean surface. A film of gutta-percha was used up over each plate, so the plan was expensive.

Mr. L. MEDLAND exhibited an old-fashioned dark slide of Marion's make, which he had found to work well, and which was extraordinarily light. It consisted of the front and shutter of an ordinary dark slide, but after the plate was put in position light was kept from it by folds of opaque flexible material fixed to the wood by one edge, but which were then laid down one upon the other over the back of the plate. It was perfectly light-tight, and should be comparatively inexpensive. For half-plate size such slides made a difference of nearly two pounds weight in his baggage over twelve exposures.

The CHAIRMAN used vulcanite slides. Two and a half of them weighed but as much as one ordinary slide.

Mr. HENDERSON exhibited sensitometer prints upon plates which had increased in sensitiveness from twenty-two to probably twenty-eight by keeping. Perhaps they were slightly damp when packed.

Mr. COWAN had tested Mr. Henderson's plates just mentioned, and there was no question as to their excessive speed.

Mr. MEDLAND spoke of the camera devised by Mr. S. C. Nash, of Harrisburg, Pennsylvania, which had no dark slides at all. Mr. Nash was coming over to England shortly, and he (Mr. Medland) had written to him that they would be very pleased to see him at a meeting of their Association.

The proceedings then closed.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual bi-monthly meeting of this Society took place on August 2 at Myddelton Hall, Islington.—Mr. J. Traill Taylor, President, in the chair.

The minutes of the previous meeting having been read and confirmed, the PRESIDENT, referring to the proceedings of the last meeting, showed two negatives taken at the Alexandra Palace with a detective camera which was fitted with the American pattern dark slide, where the shutter is entirely removed during the exposure. He had allowed the full sunlight to fall upon the dark slide during exposure, but still there was not the slightest trace of fog in the negative. He did not believe that there was any necessity to attach so much importance to the finders usually fitted to detective cameras. He had made a great many exposures while holding the camera in his hand, and could point it so accurately as to be able always to place any given object in the centre of the plate at will, and he found no difficulty in keeping the camera perfectly level.

Mr. S. G. B. Wollaston exhibited a diaphragmatic shutter invented by Mr. C. Wollaston, and also several prints from negatives taken with it. The principal advantages claimed for this shutter being that it would give an exceedingly rapid exposure, which had been ascertained by experiment to be less than the one-hundredth part of a second; that the shutter, being placed between the lenses and opening and closing at the centre, the utmost evenness of illumination was obtained; that the shutter did not in the least degree cause the camera to shake; and that in using this shutter there was not nearly so much falling off of definition at the margins of the negative as was the case with a great number of shutters sold in the market.

Mr. OCTAVIUS SMITH then read a paper *On Systems of Numbering Photographic Lenses and Diaphragms* [see page 505], illustrating the laws of light connected with the subject by means of diagrams on the blackboard and by models.

Mr. F. W. HART said that when he commenced photography there was no such thing as being troubled about exposure tables and numbers of diaphragms and lenses. It was only within the last few years that photographers had commenced to worry themselves about these matters. In the old days a

photographer looked at the ground-glass screen of his camera for a short time, and after a little reflection said, "Well, that will take fifteen seconds," or a minute, as the case might be, and it was seldom that he found himself wrong in his calculation. Now it was customary to work out the exposure necessary with the aid of four or five very complicated tables. He advised everyone to go back to the old method and trust to experience. At first they might spoil a few plates, but after a time he was sure they would get on much better than with the tables.

Mr. L. MEDLAND had tried working with the aid of exposure tables, but could not succeed with them. He remembered once being out with a friend who had a strong belief in their usefulness, and he got him to calculate an exposure from his tables, and found the resulting negative so much over exposed as to be almost useless even after intensification.

Mr. F. W. COX said he knew Mr. Medland's friend, and thought it only fair to say that he was a very successful photographer and produced excellent work with the aid of exposure tables.

Mr. GEORGE SMITH thought that the lecturer had complicated his paper by speaking of the principal focus of a lens, and also that he had been too exact in working out the various formulae in the manner he had done. He would like to correct Mr. Smith, and denied that there was the amount of error which had been stated in the formula which he gave in connection with the area system. He did not say that it was mathematically correct, but it was quite near enough for all practical purposes. In the area system he had adopted $\frac{1}{4}$ as the unit, as it was the largest aperture used in ordinary landscape work, and he could not see that it would be at all advantageous to adopt $\frac{1}{2}$ as the unit.

Mr. A. MACKIE could not help noticing how extremely accurate Mr. Smith had endeavoured to be right through his paper. He did not think the subject so important as some people attempted to make it, for after the tables had been most carefully compiled there were such matters as the rapidity of the plate and the chemical quality of the light to be guessed at; and, taking all things into consideration, it was, in his opinion, far easier to make a correct exposure by one's experience than by the use of exposure tables.

Mr. TAVENER considered that there was very great latitude in exposure provided the developer was regulated accordingly.

Mr. GEORGE SMITH said, that as the exposure depended so much upon the distance of the object from the camera, he considered Mr. Howard Farmer's tables were the most useful.

The PRESIDENT said that many photographers, after having made a correct estimate of the necessary exposure, were unable to calculate the time in cases of short exposures, and recommended a system of mental calculation instead of using a watch.

On the motion of the HON. SECRETARY, the further discussion of this paper was adjourned until the next meeting, which will take place on the 16th instant. Visitors are invited.

An excursion was arranged for August 13 to Wood-street, Walthamstow, for Epping Forest. Trains from Liverpool-street every half-hour.

A vote of thanks to Mr. Smith for his paper terminated the meeting.

Correspondence.

Correspondents should never write on both sides of the paper.

AUGUST MEETING OF THE PHOTOGRAPHIC SOCIETY OF FRANCE.—OPENING OF THE EXHIBITION AT PARIS ON THE 12TH INSTANT.—A FORMULA TO PREVENT THE ROLLING UP OF PROOFS.—CAN DIAPHRAGMS BE CHANGED AT WILL WITHOUT REFOCUSING?—PROPOSITION MADE BY PROFESSOR STEBBING FOR A PHOTOGRAPHIC CONGRESS AT PARIS DURING THE EXHIBITION OF 1889.—ALSO PHOTOGRAPHIC CONVENTIONS AS THOSE OF DERBY AND GLASGOW FOR FRANCE.—DISCUSSION ON THAT SUBJECT.—A MODIFIED CAMERA.—GELATINO-CHLORIDE PLATES IN THE CAMERA.—A NEW PHOTOGRAPHIC ENGRAVING PROCESS.

The Photographic Society of France held their monthly meeting on Friday evening last, M. Davanne in the chair.

M. Davanne informed the members that the Exhibition "*des Arts décoratifs*" would open its doors on the 12th instant. After having spoken of the taste displayed in the organization, and the large part allowed to photography, he continued by saying that he deplored that so few French photographers had exhibited. "Nearly all are foreigners," said he, "and it is strange indeed that our countrymen call aloud for exhibitions, and when one is at hand they are found wanting."

A Belgian has given, said the Secretary, the following formula to prevent unpasted proofs from curling up. Plunge the proof into the following solution after their last washing:—

Water	1 part.
Alcohol	4 parts.
Glycerine	3 "

A great discussion took place upon whether or not a subject could be focussed with a certain size diaphragm in the lens, and this diaphragm be then changed for another without refocussing being required. As a great divergency of opinion was manifested on the subject, it was agreed that a theoretical paper should be solicited in the *Bulletin*.

Professor Stebbing made the following communication:—

"M. LE PRÉSIDENT ET MES COLLÈGUES,—I have lately received several letters from abroad expressing the desire that an International Congress of Photography should be held in Paris during the forthcoming Universal Exhibition of 1889. I have the honour to propose that the Photographic Society of France study this question, which interests the photographic community at

large. Such a reunion of *savans*, photographers, and amateurs would not only have an immense importance for the future of photography, but would give a certain renown to the Exhibition itself. To our Society belongs the honour to organize a Photographic Congress. I propose, therefore, that we name a permanent committee, which can discuss and enter into the views of local societies. La Société Photographique du Nord has already taken the initiative of forming an International Congress of Photography for 1889. The idea of this young Society was favourably received by the Comité Départemental du Nord. Le Commissaire Générale de l'Exposition expressed his approbation. At this point the forward movement of this above-mentioned Society completely ceased. They say that it is the duty of the Paris Committee to go forward and propose the programme of the subjects to be discussed at the Congress. They will willingly join with their colleagues of Paris.

"At the same time that the commission named by our Society prepare the way for the Congress, I propose that they consider the advisability to establish yearly meetings of the photographic community such as take place in England. The value of such Conventions has been amply proved. The Photographic Convention of the United Kingdom has just had a complete success at Glasgow. In the month of August, 1886, the first assembly of the Convention took place at Derby. Seventy members were present. At the second meeting of the Convention at Glasgow last month two hundred members responded to the appeal. During the seven days which the Convention lasted the evenings were devoted to the study of scientific subjects. A great number of papers were read and demonstrations given, apparatus and proofs exhibited, &c. The days were employed in making excursions in the environs under the direction of local members acquainted with the surrounding country. Numerous landscapes were taken as *souvenirs*. The local committee had made previous arrangements with the hotel keepers as to the price of board and lodgings, as well as the excursions. Every expense was foreseen. The happiest results have attended these fraternal meetings, and I see no reason why similar reunions should not be organized in France, and I hope that the Photographic Society of France will receive with due attention the proposition I have the honour to lay before them this evening."

The Chairman tendered his thanks to Professor Stebbing, and informed the members that the Belgian Society of Photography had taken the initiative of a Photographic Congress, and that the King of that country had taken a lively interest in the subject; that letters had been exchanged between every Photographic Society of Europe; in fact, that the subjects to be treated, especially relating to a standard light, had been discussed. He (the Chairman) did not think that the French Society of Photography could seize upon the laurels of the Belgian Society. Professor Stebbing made the remark that the idea of a Congress owed its birth to the Exhibition of Antwerp, and as it died with the close of that Exhibition, he did not see why the idea should not be revived, fructify, and bear fruit for the Paris Exhibition of 1889. Probably the Belgian Society would be but too happy to take part in and assist the Committee chosen by our Society. That, said the Chairman, would do away with every difficulty.

M. Arwin presented a half-plate camera adapted for tourists. From the body of the camera to the woodwork supporting the lens a black silk bag is attached. This part of the camera is set up very rapidly and is very light. A very short bellows joins the body of the camera to the focussing glass in order that, if required, different lenses may be employed. M. Arwin names this apparatus "*Le Polygraph*." This demonstration caused some acrimony and discussion among the cabinet makers present as to legal rights, &c.

M. Tondeur exhibited some negatives taken in the camera on gelatino-chloride plates; he employed the phrase, "the exposure is out of all proportion with gelatino-bromide plates." I failed to see the value of this presentation. I learnt that the exposure in the camera was five minutes! He said he got better results as to detail than if he had used gelatino-bromide plates with an exposure of one-twentieth of a second.

The most interesting subject of the evening then came on—a new and novel photo-engraving process invented and patented by M. Sartirana. Every one acquainted with copperplate engraving has seen or heard of the machine employed to plough parallel lines upon the surface of the metallic plate. These lines are regular, and of the same depth throughout; the cutter or plough being made so as to slide along the steel ruler. On the other hand every one who has dabbled in photography, especially in the Woodbury photo-printing process, knows that a prominent relief of a given image can be obtained in gelatine. We have here two instruments: First, a line-ploughing machine; second, a negative or positive in relief. M. Sartirana, in contemplating over the subject, came to the conclusion that the one could be adapted to the other so as to give birth to a new photo-printing process. This is how he operates in order to obtain an engraved plate. Upon a well-levell'd table the cutting apparatus is placed, on one side of it is firmly fixed the photographic image in relief. Now, instead of the cutting plough being fixed to the steel ruler so that it cannot rise or fall when made to cut the ridge or groove upon the metal plate, this cutting plough is allowed to rise or fall; by this means the groove across the metal plate is not of a regular depth, as is absolutely necessary in the process for which it was invented. Now a mechanical mind can seize immediately the working of this new photo-engraving process, and I should not be surprised that it has been commercially worked long ago, seeing how simple and easy it can be worked. To the sliding apparatus which holds the cutting tool or plough is adapted a lever; at one end of this lever is fixed the cutting tool, to the other a stump tool in ivory. Everything being ready the operator draws

the sliding apparatus along the steel rule, the stump tool passing over the uneven surface of the gelatino-relief lifts or lowers the cutting tool, and the cut groove is a counterpart resemblance of the hills and valleys of the image in relief. Only the hills on the gelatine film form valleys on the engraved plate.

I send on to the office of THE BRITISH JOURNAL OF PHOTOGRAPHY a specimen proof printed off a block engraved by this process.

The Chairman informed the members that the next meeting of the Society would take place on the first Friday of November.

59, Rue des Batignolles, Paris.

PROF. E. STEBBING.

COPYRIGHT AND OWNERSHIP OF NEGATIVE.

To the Editors.

GENTLEMEN,—In the correspondence which has appeared in your columns on the portrait negative, in your issue of March 25, A. Debenham, of Ryde, I. W., writes, "It is usually taken for granted that a photographer's negatives form an important item in his assets," and in your issue of May 20 Mr. Bashe, of Sheffield, states: "Photographers go to a great expense in fitting up rooms on purpose for the care of negatives, which means a good sum of money yearly in rent, some of our large firms requiring a building for this purpose alone." These statements refer to the portrait negatives taken in the usual course of business. Again, I read in THE BRITISH JOURNAL OF PHOTOGRAPHY ALMANAC for 1882, in an article on copyright by Mr. Pearce, "It is only in accordance with common sense that a person who sits for a portrait should have some control over the multiplication of copies," and in a leading article in your issue of March 19, 1886, the writer says, "When an artist is paid for taking a portrait he has no moral right to use the negative for any purpose of his own. He has been paid for his work, and there is, or ought to be, an end to the transaction."

From these statements it is evident that there is a misconception by some photographers of the rights they possess to the portrait negative. For their benefit, perhaps, you will supplement the correspondence with extracts relative to this negative from an article explanatory of the Law of Copyright in Photography, and contributed to THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1869 by P. Le Neve Foster, M.A., Barrister-at-law and Secretary of the Society of Arts, a distinguished amateur photographer.

"For immediate disposal, a well-established photographic business in full working order, with dwelling-house, glass room, apparatus, &c., complete with five thousand first-class negatives."

"Such advertisements are constantly seen in our photographic journals, and yet I am inclined to think from conversations and correspondence I not infrequently have had with photographers, that, simple as the transaction appears to be, both sellers and purchasers have no clear ideas of their rights as regards the negatives with which they are dealing. I propose to call attention to a few points which should be considered by both parties when engaged in such transactions as the above."

"As regards the second division of negatives, viz., those which the photographer has been employed to execute, they will include the general run of portrait negatives taken in the usual course of business. In every such instance, though the materials of which the negative is composed are the property of the photographer—that is to say, the glass and collodion film with the picture impressed upon it—yet the copyright becomes the property of the person on whose behalf it was taken 'for a good and valuable consideration,' and the photographer has no right whatever to print a single copy from any such negative, except by the order or license of the party on whose behalf it (the negative) was made. It would be such a breach of duty on the part of the photographic artist as would render him liable to all the penalties of the Act against pirates of copyright."

"And here it may be well to caution photographers generally, and particularly the purchasers of negatives, to be especially careful about the registration of copyright in any photograph. There is reason to believe that it is by no means unusual for photographic artists illegally to claim and register the copyrights in commissioned photographic works. This observation especially applies to portraits of celebrated persons. Nothing can be more improper or unjust; and in every case therefore, where the copyright to a negative is purchased, and especially from a photographer, it should be carefully ascertained that he really is the proprietor of the copyright. For that purpose, the registration at Stationers' Hall is worthless if it should turn out upon inquiry that the photograph registered was a commissioned work, and, consequently, that the copyright originally vested in the employer and not in the photographer. Again, don't let a photographer imagine that because a negative lawfully remains in his possession, he can legally do what he likes with it. He may, it is true, if he like, clean the film from the glass and use it again, unless, indeed, he has, as is often the case, undertaken to supply subsequent copies at certain rates of charge. In this case, the question arises, How long is he bound to retain the negative on the glass for this purpose? The answer to this will depend on the circumstances of each instance, namely, the terms and conditions under which the negative was made. All that can be said generally is that, in the absence of any express stipulation to the contrary, the law would hold the photographer liable only to keep the negative for a reasonable time."

"In dealing with the Copyright question generally, it will facilitate arriving at a just conclusion always to bear in mind that the negative is

one thing and the copyright another. The two do not, upon the sale of a negative, necessarily pass together; that is, the sale of a negative does not transfer the copyright, and vice versa. In short, the negative and copyright are perfectly distinct; the right to use the negative, which is, in fact, the copyright, is the point never to be lost sight of, and which copyright, in the case of commissioned works, can only be acquired by the photographer under an agreement in writing, which must be followed by registration at Stationers' Hall, as previously stated.

"I may add that copyright is made personal estate by the Act; consequently, on the death of the proprietor, it vests in and may be dealt with by his executor or administrator, like any other personal property."

"The proprietorship of every copyright, and every assignment of it, must be registered at Stationers' Hall."—I am, yours, &c., J. F.

BACKING PLATES.

To the Editors.

GENTLEMEN,—Your amateur friends, and others who want a good backing for their plates to cure halation, need not go messing about with gum, glycerine, and ivory black.

A very good substitute may be found in Newman's *slow-drying* moist lampblack, which I have been in the habit of using for some time. A little squeezed out of the tube can be spread with the finger where required; and as I seldom take a view without a preliminary inspection, and a slight sketch in pocket-book to show where to back the negative, I do not find it at all necessary to smear the whole of the back of the plate.

Even when the preliminary inspection is not available, it is almost always sufficient in landscape work to cover the upper part (lower part in camera back) where the sky will probably come. And in church interiors a dab in the centre, where the East window is usually found, will answer nineteen times out of twenty. Perhaps, probably, the twentieth will be the most important of all; but I really don't feel equal to blacking the whole of the backs of all twenty plates, with the privilege of having to clean it all off. The colour easily wipes off with a damp cloth, and if it is objected that using the finger is a rather dirty job, there are two simple remedies. The first is to use somebody else's finger, the credit of which suggestion is due to an eminent scientific gentleman, the late Sir Isaac Newton, who used a lady's finger as a tobacco stopper; but where that is not available, as in my case, one of the common indiarubber finger-stalls answers perfectly well.

I have not your article at hand to refer to, but think you recommend this as a more perfect backing than asphaltum. My experience is the other way; and in any very difficult case, I prefer a solution of asphaltum, or what I suppose is such, sold by Hopkin & Williams under the name of liquid jet. It is very cheap, dries in a few minutes, and is easily removed with a little benzole or chloroform. Of course, this would be a horrid job if all over the plate; but it is only in the case of bad east windows, or arch-like, whose position is known, that I use it. This jet was recommended in one of the JOURNALS or ALMANACS many years ago, and I have used it ever since; but these sort of things seem forgotten and resurrected periodically.

R. SEDGFIELD.

Norbiton, August 6, 1887.

To the Editors.

GENTLEMEN,—I have read with much pleasure your remarks on *The Best Mode of Backing Plates*, and would like very much to adopt the method you recommend, but I am afraid of my dark room. Like many other amateurs, I do not possess a room set apart and fitted up for the purpose, but am obliged to be content with one which is generally used for other purposes, and although it suits very well for development (by taking care that the plate is covered as much as possible) I am sure that the exposure of plates in it sufficiently long to coat and dry would result in fog worse than the halation to be cured.

Can any of our dry plate makers come to the rescue? In their manufacturing fitted up with every mechanical appliance and perfect immunity from light, backing plates after coating would entail very little extra trouble. I am sure one or two shillings per dozen extra would pay the makers, and their issue would be much appreciated by many others who work under the same conditions as—Yours, &c., B. Sc.

Plymouth.

FIFTY SITTINGS FOR A PORTRAIT.

To the Editors.

GENTLEMEN,—In your issue of July 22 I put the question to Mr. R. Barrett, "In what way a portrait painter may avoid or shorten the sittings nowadays?" as alleged by him in an article headed *Colouring as Applied to Photography*. As there appeared no reply, I presume that it is a somewhat difficult task to answer the question, and in the interest of the photographic art, as well as of the art of painting, I consider myself justified in contradicting the opinion of Mr. Barrett, and to say that a portrait painter cannot receive any assistance by aid of photography. A painter is bound to study with his own eyes the forms in combination with the many different shades of colours, and the transparent individuality of the skin, &c., to obtain a resemblance of nature in

his picture. All painting done in another way can only be an imitation, and without any value relative to art. From this point it is also easily understood that a photograph may have and has value by itself, but cannot be improved by retouching, though it may be a trick to please uneducated eyes. It would be the same thing if one would carefully take out all the strokes of the brush visible in a painting, and making a very smooth surface all over, but surely spoiling the peculiarity of the original.—I am, yours, &c.,
A PAINTER.

Liverpool, August 8, 1887.

[Our correspondent is quite mistaken in saying that painters receive no assistance in their works from photographs. We know of innumerable instances to the contrary.—Eds.]

TITLES ON NEGATIVES.

To the Editors.

GENTLEMEN,—Referring to the answer you gave "Perplexed" in last week's issue, may I venture to suggest that an easy method of printing titles into photographs is to write them on vaselined tissue-paper in some thickly mixed non-actinic colour, and then simply to reverse them on the negative?—I am, yours, &c.,
C. B. VANDELEUR.

Curragh Camp, Ireland, August 4, 1887.

FRILLING.

To the Editors.

GENTLEMEN,—I should be glad if you would tell me what to do when in the middle of developing, &c., a lot of negatives they all unexpectedly start frilling; some even come off the plate in a mass of film.—I am, yours, &c.,
W. PEACOCK.

[See leading article.—Eds.]

Exchange Column.

I will exchange a stereoscopic camera, twin lenses, London make, for a half-plate set.—Address, W. SAUNDERS, Dickleburgh, Seole.

Wanted, oak studio table in exchange for pillared balustrade with iron pedestal.—Address, T. COFFE, 39, Banktop, Blackburn, Lancashire.

Will exchange half-plate camera stand for eight film carriers, half-plate size, or lesser number and difference in cash.—Address, A. LIDDLE, 69, New North-road, London, N.

Wanted, a few lessons in solar enlargement and carbon printing on opal by an amateur Indian, in exchange for a set of thirty best Indian views and costumes.—Address, A. H. T., 13, Colville-gardens, W.

Will exchange a compound lantern condenser, also a quarter-plate portrait lens screwing into a brass tube for lantern, for a rolling press or a lantern-view or quarter-plate camera of very long focus, and with some double dark slides.—Address, K., 23, Chancery-road, Herne-hill, London.

Answers to Correspondents.

J. W. RAMSDEN.—Received. The slide is being tested.

W. R. McDOWALL.—Thanks for the enclosures. The invention seems practicable.

W. D.—Messrs. Marion & Co. will supply the brass rims in any quantity you may require.

THE MOUNT (Ackworth).—You had better interpose blotting paper between the vulcanised pad and the sensitive paper in future. No doubt those prints which showed evidence of discolouration were longer in contact with the indiarubber than the others.

J. FAWCETT.—Without you take advantage of orthochromatic photography you will not succeed in getting a better copy of the picture. We know the picture well, and can therefore say positively that nothing better than the example sent can be obtained except by the means indicated.

LANTERNIST.—The Art Union print is copyright, and you will infringe it by reproducing the picture as a lantern slide. It is quite possible that the proprietors may give you permission to copy it as a lantern slide, though it is scarcely probable that they will. Write to them and ask the question.

B. M.—The system is a bad one, yet it prevails, though, we hope, not to the extent you surmise. Most operators, particularly those of the better class, are above that sort of thing. We cannot publish your letter under a *nom de plume* or under your signature in its present form. It would be a libel on a very honourable body.

S. A. H.—We are not surprised at the reply received. Those who work any of the different photo-mechanical processes as a business will not impart the whole of the knowledge they have acquired by practice and careful study without a substantial consideration. Why should they? With them it is simply a matter of business, and not a hobby.

SHRIPS.—1. If the operations were carefully carried out there should be neither brown stains or white spots. They evidently proceed from faulty manipulation.—2. The lens has nothing whatever to do with either the thinness or the density of the image, that rests with the exposure and development.—3. The iris diaphragm is about as good as any other.

COL. GRUBBS, R.A.—The kind of level described can be obtained at most mathematical instrument makers or at the better class of tool makers. They are not, however, considered so good as the ordinary spirit level. The "Eastman strippers" are supplied by the Eastman Company, 13, Soho-square, W. Write to them direct if you fail to obtain a supply otherwise.

H. R. H. writes: "Will you please tell me, in your 'Answers to Correspondents,' what is the best mountant to use for mounting photographs face down on glass, as I find starch is not suitable for my purpose, namely, making medallions?"—The most suitable material for the purpose is gelatine, and the best kind to use is that mentioned in a sub-leader, namely, Nelson's "No. 2 Soluble."

B. C. C. asks: "What is the cause of opaqueness of negative after ammonia development, and a sort of milky appearance of the print from the same negative after toning?"—Without seeing the negative it is impossible to say the cause of the opalescence. The negative being defective fully accounts for the prints being defective also. Unless the negative be perfect it is impossible to obtain perfect prints therefrom.

R. B. Y. wishes to know how large pictures on paper with a rough surface like that of drawing paper are produced. He says he has seen some which appear very suitable for finishing in crayons, and he would like to try his hand in that direction.—Pictures on rough paper are produced either by the carbon process or by the gelatino-bromide process. Those who supply either class of picture will furnish our correspondent with what he requires.

A. G. wishes to know the reason why the sides of a street view are so much sharper than the sides of a landscape taken with a lens under similar conditions in both cases.—In reply: The lens projects its image on a curved field, and as the sides of the street view are much nearer the lens than the centre of the subject, it follows that there is an elongation of the marginal lines sufficient, by the law of conjugate foci, to project the image on a flat field, which is not the case with the sides of the landscape.

C. BANYARD writes:—"Will you kindly tell me how I can alter a French lens that I have? It throws a good sharp picture on focussing glass, but when taken the picture seems out of focus, but seems to improve the smaller stop I use."—In reply: The lens is over or under corrected, probably the former. For a portrait combination, test the front lens for the fault, and if it prove to be the delinquent, alter by regrinding the contact surfaces to another curve, if you can; but if you cannot, then place it in the hands of a competent lens grinder. The simplest way to utilise the lens is to ascertain the difference between the visual and chemical foci, and rack the lens in or out accordingly.

ETHEL CONSTANCE MAY (Bad Wildungen, Germany).—We are not conscious of the receipt of any previous letter. We do not know the address of the maker of Perron's dark slide, nor whether it is yet an article of commerce. It is, we believe, the same slide that was described in our issue of April 15 (page 238) by our able French correspondent, Professor Stebbing, as having been exhibited at a meeting of the French Photographic Society. So that you will perceive it was noticed in our pages anterior to the other publication to which you refer. It is probable that a note addressed to Professor Stebbing will ensure those particulars you desire to know, but of which we are ignorant.

F. W. BRETT asks: "What is the cause of the denser parts of a negative when dry having a raised appearance in proportion to their density, and on the shadows a kind of crystalline deposit? The plate was developed with the sodic-potash developer (page 144 of the ALMANAC for 1887), and cleared in a bath of citric acid, sulphate of iron, and alum. I developed two plates at the same time, but only one of the negatives showed this defect. Any suggestions with a view to remedying this will be much esteemed."—The denser portions of a negative have usually a higher relief than the thinner ones, but the crystalline deposit on the shadows is due to imperfect washing; the salts which ought to have been washed out have crystallised on the surface. The reason why one of the negatives shows it and the other does not is that the washing was more complete in the one case than in the other.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, August 17, 1887, will be on *Organizing Photographic Outings*. Saturday outing at Pinner. Trains every half-hour.

FROM Mr. F. K. Hurman, Ryton-on-Tyne, we have received a graphic programme of a picnic, produced at his own expense by the president of a local club, and presented to the members to the number of a hundred and sixty, the President being an enthusiastic amateur photographer. It contains several portraits, groups, and scenes printed in platinotype.

NOTICE.

WITH our issue of to-day we present a group of some of those members who went to Tarbert on the occasion of one of the numerous excursions indulged in during the week of the Photographic Convention of the United Kingdom. Owing to the strength of the temptation presented by ruined castles, fishing villages, and charming scenery in general, only a limited number of the excursionists were present when Mr. Stuart erected his camera, but for all that the group comprises several men of mark. We shall furnish a key next week.

No. 1424. VOL. XXXIV.—AUGUST 19, 1887.

SOAKING PLATES BEFORE DEVELOPMENT.

A CORRESPONDENT calls attention in another column to what he considers a discrepancy between his own practice and the experience of others who have written on the subject, inasmuch as he has found, contrary to published statements which he has had previous reason to doubt, that a preliminary soaking in plain water before development causes the plate to develop more rapidly than if the developer be applied directly to the dried film. Whether such is or is not the case, and where our correspondent has probably been led astray, we shall attempt to show.

In the earlier days of gelatine plates, following no doubt upon the practice which prevailed in connection with *collodion* dry plates, it was considered necessary, and it was the universal custom, to prepare the dry surface of the gelatine to receive the developer by soaking it for a minute or two in water. In the old dry *collodion* days this was undoubtedly a very necessary precaution, as could readily be demonstrated; indeed, the mere wetting with water was in itself insufficient to restore to the dried film the requisite degree of porosity to enable the developer to penetrate it. A first application of alcohol, more or less dilute, was needful to soften the horny skin of *collodion* enveloping the particles of sensitive material, and almost entirely protecting them from the action of the aqueous developer to which it was nearly impervious. The alcohol, however, exercises a certain penetrating power, causing the *collodion* film to swell and open its pores, thus giving free access to the aqueous solution by displacement.

In order to demonstrate not merely the utility but the absolute necessity of this preliminary treatment with alcohol, it is only necessary to take a dry *collodion* plate possessing a moderately horny film, and, after exposure, to treat only a portion of the surface with alcohol, washing the latter away thoroughly before commencing to develop. Upon development it will be found that while the portion treated with alcohol gives a dense and satisfactory image, the other not only develops slowly, but will give nothing but a feeble, miserable, and foggy image, however long the operation may be continued. The fact is the *collodion* is so impenetrable to water, and so thoroughly protects the particles of bromide from the action of the developer, that only a comparatively small number of them come under its influence, and those mainly the coarser particles which lend most to the production of fog. We are speaking now principally of dry films prepared with organifiers of but slight viscosity, such as tannin, for where such substances as gum or gelatine are employed they partially fill the pores of the wet *collodion* film and enable it to swell and regain some of its porosity in water alone. Still,

even these latter are better for the use of alcohol. The more modern *collodion* emulsion plates possess films which are naturally more porous and penetrable to water, and may, consequently, sometimes be developed without alcohol, though the results are nearly certain to be inferior.

When we turn to gelatine plates the absolute necessity for this preliminary soaking is not so obvious. Gelatine, though insoluble in water at the ordinary temperature, absorbs it with the greatest avidity, and therefore the developer, being aqueous, of course requires nothing to prepare the way for it into the film. In fact, the surest way of getting the solution quickly right to the back of the film is to apply it to the dry surface, for then it is rapidly sucked up by the gelatine instead of more slowly finding its way in by displacing the water already absorbed. Still, as we have said, it was the early practice to resort to this first soaking in water which, under certain circumstances even now, as then, may have its advantages. In developing film or paper negatives and prints, for instance, the preliminary soak in water is given not so much as affecting the sensitive film, but because it softens the negative and makes it lie flat, so conducing to ease and regularity of development.

We have just said that the soaking in water may, under some circumstances, prove beneficial, and we may at once explain that those conditions are mainly connected with the condition and quality of the emulsion or film. The benefits derived may be not only acceleration of development as described by our correspondent of this week, but may actually result in the removal of fog. In every such instance, however, we should set the effect down to a faulty emulsion in the first place.

If a perfect film be taken—that is, one consisting only of pure silver haloids and undecomposed gelatine—the effect of the preliminary soaking can be readily demonstrated by the very simple experiment of soaking only a portion of the plate for, say, two minutes, and then plunging the whole into the mixed developer. As a fact readily verified, and not as a “disputed point in development,” the result may be stated as follows:—The image will commence to develop first upon the unsoaked portion of the film, and will gain some strength and detail before the remaining part shows any sign. As the application is continued, the image on the unsoaked portion gradually makes its appearance, and as it progresses slowly overtakes the first, and when the development has been carried as far as possible there will be little difference between the two halves when the negative is viewed by transmitted light, though, with most plates, there will be a slightly noticeable difference on looking at the surface. In fact, the unsoaked parts of the

film appear to commence vigorously, the energy dying away as development proceeds, while, in the portions that have received the preliminary soaking, the action is slower in commencing and proceeds more gradually, and without falling away so rapidly. There is little, if any, difference in the amount of detail or the density ultimately attained, the effect being merely started and completed more rapidly in the one case than in the other.

It might be supposed that the additional energy exhibited by the dry portion of the film would be sustained throughout the operation, and that the ultimate result would prove beneficial so far as apparent exposure is concerned; but against that supposition, and to account for the rapid waning of the action of the developer, one or two points are worthy of consideration. It is well known that a strong developer acts not only more rapidly, but also gives greater vigour, and possesses a stronger power of searching out detail than a feeble one; the soaked portion of the film under the circumstances of the experiment is virtually subjected by the action of a weaker developer, since the solution is diluted by the water already absorbed by that part of the film. This, taken in conjunction with the slower penetration of the developer, owing to its having to displace the water already absorbed, is sufficient to account for the extra initial energy of the dry portion of the plate.

But as the image develops, the bromine liberated from the reduced silver haloid enters into combination with the alkali of the developer, and though the dry film is first attacked by a comparatively stronger developer than the already moist portion, it is rapidly placed under the influence of a solution feebler in alkali and more strongly restrained, and so the superior energy of the first onset suffices in the end to counterbalance the apparent promise of greater developing effect. With most plates, as we have said, there is little to choose between the final results whether the film be soaked or not, but occasionally, from some peculiarity in preparation, a distinct difference is noticeable in the printing qualities of the negatives, and not unfrequently the advantage is slightly in favour of soaking, though invariably the action is slower.

So far we have spoken of perfect plates; but should the films be not necessarily downright bad, but contain traces of free bromide or of nitrates imperfectly removed in washing the emulsion, it is quite possible to conceive that the preliminary soaking may slightly accelerate the development. We need not point out that as bromide is a restrainer its removal from the film before applying the developer is equivalent to employing so much less restrainer, and it is pretty well known also that the soluble nitrates act to a certain extent as restrainers and that the same remark applies equally to their elimination. But it is difficult to believe that the removal of such small quantities of either as are likely to be present in dry plates—commercial ones at any rate—of the present day would suffice to neutralise the retarding influence set up by the act of saturating the gelatine film with water.

Then, again, partly decomposed gelatine, as well as salicylic acid and similar substances added to the emulsion to prevent decomposition, have a marked action in retarding the action of the developer. In the early days of gelatine plates, when "soft" gelatines, prolonged digestion, and antiseptics were in vogue, it is possible that the practice of soaking the plate before applying the mixed developer was of use.

It may also prove beneficial under extraordinary circumstances, as when plates have been kept for a considerable time,

especially in a hot climate, and the films have become particularly hard. Gelatine under such conditions absorbs water but slowly, and not always with uniformity, for which reasons the preparation and equalisation of the film by the preliminary soaking would form a distinct advantage. Similarly, if the plates have been subjected to moisture and have redried, the chances of inequality and uncertainty may be removed by similar means.

Just one other instance, which, however, is not likely to arise with commercial plates, may be mentioned to show that the soaking may prove of very decided advantage. Some years ago we prepared a number of plates by a formula in which an excess of silver figured, the excess having evidently not been thoroughly removed in washing. These plates up to a certain age gave perfectly satisfactory results when soaked before development, but would not at all stand the direct application of either alkaline pyro or ferrous oxalate to the dry film. In the course of time they became perfectly useless from decomposition.

Returning to our correspondent's letter, we can put but one construction on his results, and we have little doubt as to the correctness of our surmise. The plates being, as he states, of his own manufacture and a slight modification of his ordinary formula—perhaps a larger excess of soluble haloid than usual—have been insufficiently washed, hence the results detailed. They must have been a pretty bad case of imperfect washing, however, to behave in so noticeable a manner. There is little ground to go upon, so far as we are aware, in attributing to iodide of silver any special influence in the direction suggested. A soluble iodide might retard development, but beyond causing the films to fix slowly a properly washed iodide plate could have no further peculiarities.

SIZE AND PROPORTIONS IN PORTRAIT ENLARGEMENTS.

ONE of the most important features in a picture, a portrait in particular, is its proportions. Although painters are exceedingly particular in this respect, many photographers appear to disregard it altogether; hence pictures otherwise good are frequently ruined, simply from lack of judgment on this very important point. With portraits of small dimensions the matter is, of course, equally as important as it is with large ones, though it must be admitted it may be less conspicuous in the one case than it is in the other. Shortcomings in this direction, which might pass comparatively unnoticed by the majority of persons in a small picture, would be conspicuous in an enlargement therefrom if the same proportions were retained.

Take, for example, the cabinet picture which, as usually trimmed, measures something like five and a half inches by four, or a little more. Now these proportions are about as good as can be for busts or for three-quarter length sitting figures, and are, as nearly as may be, those which have been adopted, for similar subjects, by most of our great portrait painters for their works. But when a three-quarter or a full-length standing figure is taken cabinet size, most people have noticed how much better the picture would have looked had less background been shown on each side of the figure—particularly is this the case with portraits of gentlemen.

Again, take the *carte-de-visite*, promenade, and panel sizes—how very unsuitable are these for some subjects; and necessarily they must be, for those proportions which are best adapted to

a full-length standing figure are manifestly not good for a head and bust. However, the above are all standard sizes, and photographers are compelled to adopt them. The sitter demands a certain style of portrait, of any of these particular sizes; the artist, having no option in the matter, supplies it as a matter of business—sometimes, however, under a mild sort of protest.

As we have just said, photographers have little, if any, discretion left them in pictures of the smaller and recognised standard sizes and shapes, but this is not the case with enlargements, as in these they have some scope to use their own judgment. Sometimes by altering the proportions of a picture, or by the introduction of a little more, or maybe rather less, of the background at the sides of the figure, a considerable improvement on the original may be effected. Very frequently this may be done by introducing more or less of the figure itself.

The photographer who makes his own enlargements can always judge, by looking at the amplified image in the enlarging apparatus, the effect that different proportions have upon the picture. Therefore he can easily decide the amount of subject which, according to his judgment, it is desirable to introduce, and also the best proportions or shape of the picture. This is not the case, however, when the work is sent out to be executed, and very often the enlarger has no discretion left to him in the matter. Moreover, the order is frequently despatched without any consideration on the part of the sender as to whether the proportions of the small picture bear any relation whatever to those of the one demanded.

Let us instance the *carte* and cabinet sizes; in these the proportions are widely different. If the latter be enlarged to, say, a very popular size—twenty-four inches by eighteen—the enlargement will contain about the same amount of subject as the small picture. But not so in the case of the *carte-de-visite*. If the subject in the latter, vertically, be made to measure the twenty-four inches, laterally it will only be about fifteen inches. If, however, the subject be made to cover the full width of the paper, some of the figure, or the background above the head, must of necessity be omitted, and that not always to the improvement of the finished picture.

It is, we believe, customary with professional enlargers, unless they are instructed to the contrary, to make the subject, whatever it may be, cover the full size ordered, so that no blank paper is shown. The intention doubtless is, that as a certain size has been ordered the whole of the paper must be covered; hence many which would otherwise have been good pictures are utterly spoilt. It is true that, in some instances, much may afterwards be done to mitigate the evil by cutting off certain portions in the framing, but this, too, is frequently neglected.

There is another important point in connection with proportions in enlargements which is very often overlooked, namely, the relation of background to figure. We have before us just now a small portrait of a lady and an enlargement made therefrom. The former is satisfactory and the latter the reverse. The sitter, it may be explained, is somewhat below the average height, and the small picture conveys a very good idea of the stature. But in the enlargement the operator, probably with the view of covering the whole of the paper laterally, has introduced so much figure, and has left so little background above the head, that it gives one the impression that the sitter must have been little short of a giantess. While the small picture has a refined appearance, the enlargement is inartistic, not to say vulgar, in the extreme. Of course this might have

been avoided had the photographer, at the time the enlarged picture was ordered, sent the original print as a guide to the operator, with instructions to make the enlargement of the same proportions.

It is a very simple thing for the artist to take an impression the full size of the negative, which usually includes more subject than is required, and then to trim or mask it down until those proportions which produce the most artistic effect are secured, afterwards sending that as a guide to the enlarger. Although photographers are restricted to certain proportions in their small pictures, they are not necessarily so in enlargements, and here many will do well to use a greater amount of discretion than apparently they do at present.

This morning (19th) will have occurred an eclipse of the sun, only partially visible in this country, and at an inconvenient hour for popular observation. Seeing that the sun would rise at seven minutes to five, the eclipse be over at six minutes past five, and that only a small portion of the disc would be invisible, it is not likely that any of our readers will have attempted photographic snap-shots at the phenomenon. But enthusiastic *savants* never willingly let slip any such opportunity of adding to the limited sum of knowledge obtainable only on such occasions, and expeditions have been arranged for observing and photographing the eclipse under the most favourable conditions. The belt of totality passes over Europe and across Siberia, which latter country was selected by the parties of observation on account of the eclipse there occurring at an hour when it would be free from the effects of earth vapours. Our esteemed contributor, Father Perry, left some time since *en route* for Siberia, and we learn from the newspapers that, on account of his being a Jesuit, special permission had to be obtained before he could even enter Russia.

MR. W. H. PICKERING, of Boston, Mass., communicates some interesting data to *Science* as to his photographic experience at Grenada last year, where he went to photograph the total eclipse. He states that the inner corona was satisfactorily shown with one or two seconds' exposure, on rapid gelatine plates, with an ordinary telescope lens. With a photographic portrait lens of about $\frac{1}{4}$ aperture, the same exposure enabled the outer corona to be satisfactorily shown to a distance of about half a degree from the limb of the moon. Beyond that distance the photographic power of the coronal light rapidly diminished, and exposures of from eight to forty seconds were needed.

IN estimating the intensity of the light of a gas burner, the term candle power (abbreviated to "c.p.") is of well-known use. It means a light equal to that given by the same number of candles, of a particular make and size, as the figure attached to the c.p. It is a very easy matter for any one to test for himself the power of a gas burner in this manner; but in the case of the electric light the difficulties are far greater, and the reputed power given to it by the manufacturer is usually accepted as a correct designation. But it has lately been shown by Professor Henry Morton, of the Stevens' Institute of Technology in the City of New York, that the best of a large number of so-called 2000 candle-power lights gave only 800 candle power. He assumes that the term "2000 candle power" has become a technical expression with the electric light companies to denote a lamp of from 500 to 1000 actual candle power." Hence those photographers who in arranging for an electric installation may be inclined to found estimates on reputed power, will need from three to four times the amount of light they would calculate upon!

WE have on a previous occasion spoken of the chloride of iron cell improved immensely in constancy by the addition of bromine as a recuperator of the chloride reduced in action to the ferrous condition. The expense of bromine is an objection to its use, but in the current number of the *Chemical News* Mr. Thomas Mowse states that the bromine may without injury be replaced by a mixture of a few

crystals of chlorate of potash and a little hydrochloric acid, to which a small quantity of bromine is added. The same writer states that permanganate of potash is an excellent depolariser, and that an exceedingly compact and handy little battery, especially suited for intermittent currents, electric bells, &c., is made by placing a carbon and zinc plate in a strong solution of this salt and chloride of ammonium. As there are few studios in the country without a Leclanché battery in use for bells, &c., our readers may easily try this substitute for themselves. The same writer states that the familiar Leclanché cell employed almost universally for these purposes may be regenerated to a great extent by pouring into the porous cell a strong, warm, and slightly acid, solution of the permanganate.

It has been generally thought that since the introduction of gelatine plates the productions of photographs of minute objects by means of the microscope had attained increased excellence, beyond and in addition to, an undoubted wider range of subjects; but Dr. Klein, whose authority on such matters is indisputable, besides having recently written* that, "taking photography as a whole, as applied to the representation of microscopic objects under high powers, I think that the time has not yet come when it can be said to have supplanted good and accurate drawings," has also stated "there can be little doubt that no real advance has yet been made in producing photograms that are to take the place of accurate drawings." Of course a drawing will always have the advantage over a photograph in that all planes can be depicted at once with equal sharpness; but it is clear that this effect is not alluded to in Dr. Klein's sweeping criticism, for he goes on to say "with the new apochromatic objectives and projection eye-pieces by Zeiss, better results may be looked for," clearly showing that it is technical excellence that he deems still wanting.

A COMPARATIVELY large number of photographs taken from the cars of balloons have been published at various times, and a still larger number attempted unsuccessfully to be secured. It is well known that one of the great difficulties met with in this kind of work is the rotatory motion of the balloon, and this has militated considerably against the successful experimental employment of stationary balloons holding photographic apparatus for military observation. In a recent number of *Nature*, however, an exceedingly ingenious arrangement (which has been tried with success) is described for giving steadiness to a balloon held by a rope so as to avoid, to a great extent, the usual jerks, oscillations, and rotations. The balloon is provided with an extra cover which acts somewhat as a kite (hence the descriptive term kite balloon, given to the invention), and not only is the objectionable character of the motion removed, but, instead of being depressed under the action of a high wind the altitude of the balloon is actually increased. This invention, if carried out by the military authorities, ought to render invaluable service by means of a camera actuated from below by means of electricity.

ECHOES FROM THE SOCIETIES.

"It was a pity that the question of amateur and professional had ever been raised," Mr. W. E. Debenham is reported to have said at the London and Provincial Photographic Association; "before it was recently raised photographers had always been working amicably together." Mr. Debenham is quite right, but there is some consolation in the fact that the best of both amateurs and professionals are still working amicably together, as witness the recent Convention. It is only the Ramsgate beach peripatetic and the "two-guinea-set man," as somebody recently described him, who in their respective classes are dissatisfied with themselves and the photographic world in general—the former chiefly, perhaps.

Appropos of the question that led to this remark, it is most certainly an anomaly that the sole exhibition open to "amateurs" only should be "run" by and in the interests of a trade concern. It is still more incongruous that the productions of such amateurs are exhibited, for sale presumably, in the shop window of the said concern.

The latest novelty in Society matters is the idea of a portrait group

* *Nature*, page 317, August 4, 1887.

of the members of the year. Such at least is what I hear is the intention of the Sheffield Society, and active measures are on foot to obtain the necessary portraits, to be subsequently joined together in one harmonious whole. If it is intended that this be an annual affair I think it would be wise on the part of the "Sheffield blades" if they consulted with Mr. Lachlan McLachlan on the subject. He would, perhaps, tell them that a similar picture cost him years of labour, and brought little but worry when finished.

Another new idea hails from the North Surrey Society, where its advantages were demonstrated a short time ago. This is no less than a "self-adhesive mount," a card, in fact, which combines in itself the support and the mountant. All you have to do is to place the print on the mount, press them together, and, lo! the thing is done, the picture is mounted. We only want now to make our printing arrangements complete a ready sensitised paper which, when placed behind a negative in the sun or diffused light, will be printed, toned, fixed, and *trinaed*—I really must insist on the latter, or the two-guinea-set man would not consider it "scientific" enough.

That brings me round to another "grumble" I have been going to indulge in for some time, but have refrained. Every reader of the JOURNALS must have noticed it, but to me, who am condemned to carefully read, mark, learn, and inwardly digest the reports of Society meetings, it is absolutely painful. I allude to the fact that our meetings now are little better than localised advertising centres; the business of the evening consists, in nine cases out of ten—or, perhaps, I should say the report consists—of an account of the exhibition of Mr. Jones's new camera, prints from Messrs. Ananias's "two and a half million times" plates ("which were generally considered to be really rapid"), and Mr. Somebody Else's new patent shutter, working in the two-thousandth part of a second, and in which the otherwise fatal "recoil" is diverted and ingeniously utilised in packing up the camera when the exposure is made. If a paper is read and a discussion follows, the reporter either "hashes" or suppresses it, and then has to fill out with the "padding" of the meeting in order to make up the space his Society expects to see devoted to its reports.

Things used not to be thus; the reports of Societies dealt with the scientific and practical matters that cropped up at the meetings. If Mr. Ananias enlarged upon the rapidity of his plates, and Mr. Munchausen, jun., described how he had obtained forty perfect negatives on three dozen of them, the Secretary of the Fibtown Photographic Association had the common sense to suspect, if he were not sure, that similar things had been said previously elsewhere, and that therefore to report them as novelties would only show how far behind the rest of the world the "Fibbers" were.

Seriously, I have no objection to Mr. Jones exhibiting his new camera if he has got one and is proud of it, but I do object to his getting it a paragraph advertisement in the report as an act of gratitude, perhaps for an extra five per cent. discount. The exhibition of novelties is, undoubtedly, one of the most legitimate portions of the evening's proceedings, but in reporting the meeting the Secretary should remember that what may be new and interesting in some far-off corner of the provinces may be "old as the hills" in the chief centres of the country. The rest of the photographic world are little interested in such details, but would gladly read a more extended report of an important and practical paper or discussion. If there be none such then let the reporter be content to economise space.

While on the subject of reports I would allude to another practice which seems to be gaining, that is, the reporting of opinions, perhaps thoughtlessly and lightly expressed with no idea of their going further, on purely trade matters. In this case the statement goes forth to the world—unintentioned though it may have been originally—with the sanction and authority of the Society attached to it, and much harm and injustice be done or, on the other hand, undeserved praise awarded.

As an instance of what I mean, two or three weeks ago at a provincial meeting two gentlemen "wished to lodge a complaint" against a commercial firm—I abstain from repeating names—because they had not been served as they thought they ought to be. Now I hold that their duty was to complain at headquarters, to the firm itself, and not to creep under the wing of the Society and thence hurl a bolt with fictitious force. Nobody can prevent their complaining in private of wrongs, supposed or real, nor even their mentioning in an informal

manner across the meeting table, but here again the fault lies with the reporter. It is not the function of any Society to act the part of judge and jury, trying and deciding a case after hearing only one side and with little chance of appeal. This is practically what they do, for what can be known of the facts of the case except what the complaining party chooses to lay before them. It seems to me an unfair attempt on the part of individuals to make the Society take up their private grievances, and Societies should, I think, fight against the system. The instance I mention is only one—a flagrant one I own—among many I could point out within the past few weeks.

Not quite coming under this head, but still an attempt to get the Society to fortify him with an expression of opinion, was Mr. Debenham's question with regard to the illustration in the last number of the Society's *Journal*. The Society had accepted an illustration printed by a commercial firm (I do not wish to advertise them), who appended to it their own trade description, which includes the word "permanent." Mr. Debenham wishes to know whether the permanence of the prints in question is established by the Society's statement to that effect—in other words, whether the Society intends to guarantee their permanency. The Honorary Secretary perhaps went a little beyond his functions in saying that the matter was a "slip," for having accepted the picture they were compelled to allow its producers to describe it by its recognised trade name, and in doing so accepted no responsibility whatever in the matter. Such, at least, is my reading of the matter. At any rate, on the facts as stated, Mr. Debenham could scarcely expect the Society to express an opinion on the much-disputed question of permanence.

I am not sure that it was not Mr. Edwin Cocking who was the first, or one of the first, to assist in discovering the effect of ammonia fumes in producing chronic nasal catarrh. Now he has discovered another photographic ailment, this time amounting to a decided "obliquity of vision." Negatives sharply focussed upon the ground-glass proved blurred and indistinct when developed, and, curiously enough, this only occurred in negatives taken at midday, *not* at night. It was suggested that "heat had a physiological effect on some persons, causing them to see less perfectly in the middle of a hot day than in the evening." If the time of the appearance of the phenomena were not as it is, and did I not know my old friend Cocking so well, I should perhaps have set it down to something besides "heat." However, I trust he may long retain the full use of his eyes as well as his "dose" to help us with our annual exhibition.

It is not often Nemesis turns up so quickly as in Mr. Higgins's case not long since at the North London Society. Exhibiting two double slides, whose chief advantages appeared to be that they had cost 6s. and 7s. respectively, the Honorary Secretary cruelly "rounded" on him, showing how useless they were for photographic purposes, by pushing two sheets of note-paper into them while closed!

MONITOR.

COLOURING AS APPLIED TO PHOTOGRAPHY.*

I THINK it may safely be conceded that a photograph even perfect as regards its mechanical and chemical qualities, may still be very imperfect as a work of art. The cure for this, more especially as regards portraiture, may be found in the judicious and skilful application of colour. It may have been most skilfully produced, every attention being paid to artistic *posing*, careful distribution of light and shade, and all other details, and may be fairly entitled to be called a *picture*, and a successful one, but yet as a *portrait* it may be most imperfect and untrue, many cases existing, owing to the chemical peculiarities of photography, where colour is absolutely indispensable to secure anything like a true or faithful resemblance to the original.

The manipulatory skill which enables one to imitate with more or less success the colours of a human head is not the only factor in producing successful results in painting. There is a primary knowledge, without which there will always be a weakness about our effects, and that is a knowledge of the natural value of colours. In studying the art of colouring our first efforts should be directed to gaining a thorough knowledge of the various relations and harmonies of colours, their many effects either in combination or juxtaposition.

We have rather a limited number of colours to start from, but

there is an almost endless variety to be produced from them. The primary colours are only *three* in number, but I cannot say how many various tints can be produced from their skilful blending. And this is not all, for in a picture many of the beauties will be traceable not to the tint itself so much as the harmony produced by the combinations of such colours and tints as mutually lend a charm. The endless variety of colours will be more observable in landscape than any other, and in fanciful or imaginative portraiture than in portraiture where nature pure and simple has to be imitated. Photographic colouring naturally gives the least scope of all, and yet it is marvellous the difference between the work of an ordinary photographic colourist who has never thoroughly studied the balance of colour, &c., and one who has acquired a thorough knowledge of the principles of harmonious colouring. The work of one is valueless, while the other shows that it is an adverse fortune that compels the artist to work within such cramped lines.

In portraiture, when we are a little free as to our treatment, there are many points which we must faithfully reproduce as far as possible. The most important being the colours which are represented on the model itself, we may almost consider ourselves free as to the choice of colours for the draperies, backgrounds, &c. This freedom is of very great value to the portrait painter, as by the skilful arrangement of such colours as will enhance the value and beauty of his complexions and still produce a harmonious whole, even an appearance of transparency may be secured under these conditions that with less freedom could never be hoped for.

Light is the source of all colour; without it there is none. A beam of white light may be divided into three distinct rays of different colours—red, blue, and yellow, these being the three *primary colours*, by the careful mixing together of which every conceivable hue and tone can be obtained.

White light, when decomposed by passing through a prism, produces a most beautiful effect of varied colours, which is called the *solar spectrum*. In this there are seven colours, the same as are to be seen in a rainbow, namely, violet, indigo, blue, green, yellow, orange, and red. At one time this led to the belief that they each and all were elemental colours. Later and closer observation, however, showed the mistake, proving that red, blue, and yellow were really the *only primaries*, the others being simply the result of these overlapping each other, and so producing a distinct colour, as would their mixing on a pallet.

The happy disposition of the three primary colours and their various combinations produces *harmony* in a picture—one of if not absolutely the most essential quality it can possess.

The mixing in certain proportions of any two of the *primary colours* will produce what we term a *secondary colour*. This secondary colour will be found to be *complementary* to the remaining colour. For example, the mixture of blue and yellow will produce green, which colour is complementary to red. The mixture of yellow and red produces orange, which is complementary to blue; and the mixture of red and blue produces purple, which is complementary to yellow.

In order to fix this on the mind, I would suggest making a circle, and then dividing it into six equal parts, and place a number in each up to six. Now pass a wash of red over 1, 2, 3; 3, 4, 5, blue; and 5, 6, 1, yellow. By this you will see that space 1 is coloured orange by the combination of red and yellow, and that opposite to it is the primary blue to which it is complementary. No. 3 is coloured purple by the combination of red and blue, and is opposite the remaining primary yellow, and to which it is complementary. Space 5 is coloured green by the mixture of blue and yellow, and is opposite and complementary to the primary red.

Modifications of these tints may be carried on to almost an unlimited extent with similar results, and doing so even to a moderate extent will be wonderfully effective in instructing the eye in the harmonious placing of the various colours. The combination or blending together of two secondary colours will produce what is termed a *tertiary*, and which in turn is complementary to the remaining secondary. Take, for example, the mixture of purple and green—olive is the result, and it is complementary to orange; purple and orange produce russet, which is complementary to green; orange and green produce citrine, which is complementary to the remaining secondary purple; and so on, and so on.

* Continued from page 501.

These relations of the various colours and their blendings one with another are not by any means the result of taste or fancy, but are based on sound art principles. They seem to exist as a physical necessity for the organs of vision, as may be seen by a very easy and simple experiment. Suppose, for instance, that we place a red wafer on a sheet of white paper; then steadily fix the eye upon it for a few moments, then remove your gaze to another plain sheet of paper, and in a couple of seconds a similar spot to the wafer will become visible, but of the complementary colour to red—green. This simple fact was, some few years ago, utilised by that enterprising firm, "Pears's Soap," for advertising purposes on all our leading boardings. This spot, which is called an *ocular spectrum*, will remain visible for some few minutes, until gradually the white light reflected from the paper will completely displace it. The same principle holds good all round. If the experiment be tried with a blue wafer, the colour of the spectrum thus produced will be orange; if a yellow wafer, a purple spectrum will result, and so on.

In all the endless varieties of the various combinations of colours this principle will be found to hold good. If a tint of red incline to a yellowish hue, as in scarlet, the complementary green must have a slight preponderance of blue, and so be a somewhat bluish green. Then, again, if the red partake somewhat of the blue, as is the case with a crimson, the complementary must incline a little to yellow, in other words, be a yellowish green. So numerous are the combinations, and so delicate the gradations that may be produced in this way, that it would be nothing short of folly to attempt to enumerate them.

Every primary and its complementary secondary will, on examination, be found to possess special contrasts and effects quite peculiar to themselves. Now blue is the coldest colour, and is also the most retiring, while orange, its complementary, is the warmest and most advancing. Every combination of tints as they approximate to orange or blue will be warm or cold in its effect as the case may be. It also carries the effect of approaching the eye or receding from it in a picture.

Yellow is the brightest colour, and the most allied to light. Its complementary, purple, on the contrary, is the darkest. White and black, it may be well to mention, although they most completely represent the contrast of light and darkness, are not regarded as colours. White, which naturally most assimilates with light, is supposed to represent a combination of all the colours, while black, like profound darkness, is a complete absence of both colour and light.

The most positive, assertive, and exciting of all the colours is red, while its complementary green is the most soothing and grateful to the eye.

In mixing tints it will be found that although the combinations of two primary colours produce a new and perfect hue, every subsequent combination will tend to produce neutrality. It is thus that neutral tints are formed, and they will be found invariably to more or less possess the special characteristics of the primaries to which they are most allied.

The effect of contrast is produced by the skilful placing of the complementary colours in juxtaposition. They mutually enrich each other, thus producing what is termed the harmony of contrast. Purple and yellow, for example, of equal purity and intensity, will each become brighter by contact one with the other. The yellow, gaining intensity by the extra yellow rays reflected by the purple, and the purple gaining additional richness from the purple rays emitted by the yellow. Similarly, all neutral tints placed near full hues will seem to be tinged with the complementary colour of such hues. Thus a grey placed in close proximity with red, it will seem to become a kind of greenish grey, green being the complementary of red. This will show how important is the judicious arrangement of the various colours, as on it depends the brilliancy and harmony of the entire picture.

(To be continued.) REDMOND BARRETT.

PHOTOGRAPHY IN JAPAN.

A FEW words as to the condition of photography in Japan may be of interest to some, and particularly to any who may think of visiting the country.

I arrived here only a fortnight ago, but was not allowed to remain long in ignorance of the fact that in matters photographic, as in others, the Japanese are coming well to the front.

Before entering on this question, however, a few words on another. There are often discussions as to packing of plates and of apparatus for long voyages. As I have come about 12,000 miles without suffering any loss beyond the breakage of the ground-glass of one of my cameras, and this in spite of the fact that my boxes received the very roughest usage, it may be interesting to know how the things were packed.

Two cameras, one 12×10, the other 6½×4½, and seven lenses—the largest a 3¼-inch portrait combination, the smallest a portable symmetrical of 10-inch focus—were placed between two layers of clothes in a large Saratoga trunk. I took only a few dozen plates with me, some of 12×10 inches, the others of 6½×4½. These were packed in the boxes with paper-lined metal grooves made by Arundel & Marshall, of London. I think these boxes decidedly deserve a good word to be said for them. Their convenience is great; the grooves being metal, the boxes may be often refilled; and they seem to allow of very rough usage without being themselves damaged or allowing the plates to be broken. The boxes were placed like the cameras, between layers of clothes in the Saratoga trunk, and the way in which this trunk was treated was such that I scarcely expected to find a whole plate when I opened it. An American porter's idea of how to move about a box when it is too heavy to lift it appears to be to roll it over on its ends, top, and bottom. It is not a cheering sight to see a box which contains cameras, plates, and lenses going bump, bump in this fashion along a stone floor; but there is no help for it. Remonstrance has no effect whatever. This sort of treatment was repeated at each of some six or seven "depôts" on the way across America. It was bad enough, but worse was to come. All luggage had to be transferred in Yokohama Bay from the steamer to a small tender, the water of the Bay being too shallow to allow large vessels to come close to shore. My unfortunate box, being very heavy—about 300 pounds in weight—was being lowered in rope slings over the side of the ship; it had only got well over the edge when it slipped from these, and fell a height of about eight feet on to the deck of the tender. Of course I expected that the 12×10 plates, at any rate—they being supported only at their ends in the grooves of the box—would be smashed to bits. I was, therefore, agreeably surprised to find that not a single plate, either large or small, had suffered. It is on this account that I think the boxes I have mentioned really deserve to have attention called to them.

A few exposures were made on board the steamship "City of Sydney," whilst crossing the Pacific. The Pacific, by the way, scarcely kept up its reputation for peacefulness, and it was only as we neared Japan that there was a day calm enough to make the manipulation of a camera on the deck at all a promising performance. It was at this stage, when I was about to expose on board the ship, having unpacked my box for the purpose, that I discovered the breakage of the ground-glass of one of the cameras. No ground-glass was to be had on board, nor was any flour emery, with which a piece of plain glass might readily have been ground; so I had to make shift by taking a gelatino-bromide plate, soaking the film till it swelled, melting it by placing the plate on the corner of the high-pressed cylinder of the main engine, and allowing the greater part of the emulsion to run off, thus leaving a thin film.

I should not have mentioned the exposures on board ship but that I learned a lesson from them—namely, that on account, probably, of the great amount of reflected light from all directions, and the consequent absence of any deep shadows, a very short exposure only is needed for groups, &c., on board ship. This might have struck me before, rather than after, I had made some half-dozen exposures, but it unfortunately did not; and I found that plates exposed on groups in diffused light were almost hopelessly over-dense with times of half to quarter second, and stop No. 16 U.S. (⅛), the plates being rapid, but not extraordinarily so. One-half or one-third of the exposure would have been sufficient.

I had not been five minutes in the Grand Hotel, Yokohama, when a *Guide to Yokohama and Tokio* was presented to me. On looking at it, I found that the guide was got up by an enterprising photographer in Yokohama. I soon had an opportunity of judging of the quality of work turned out by him and by two or three other professionals, most of them Japanese, and came to the conclusion that it was at least up to the average of English landscape work. Nor is this to be wondered at, for there is a vast choice of subjects here of a most photographable nature, and the light is exquisite. It is an almost universal practice to colour landscape photographs in Japan. In so great disfavour is the colouring of prints on albumenised paper generally held at home, that it is very difficult to overcome the strong prejudice that one feels against the practice; but it must, on consideration, be admitted that, in Japan, it is at least a much more excusable practice than in England. Landscape photographs are generally purchased here, by visitors, to take home to give some idea

of the country to their friends, and, as a matter of fact, no idea—or, rather, only half an idea—can be given if the element of colour be left out of the pictures. Colour is of importance enough at home; but it is of very much greater importance here, where its vividness is something it is impossible to describe. Especially is this true of the greens. The most gaudy colouring cannot show them as more brilliant than they are.

Then, again, the colouring of photographs has probably fallen into disrepute rather because it has been badly done than because there is anything essentially vicious in a painted photograph, and the Japanese are well known to be most skilful in the use of colours.

In the Gallery of A. Farsari & Co. I had the pleasure of seeing the native artists at work. They were to be seen busily engaged in a large room, each artist in the position almost universally adopted by a Japanese for his work, namely, squatting on a straw mat.

Straw mats form almost the sole furniture of Japanese rooms, either for dwelling or for working. The men, women, and children squat on them during the daytime, and sleep on them at night, and very comfortable they are to sleep on; but the squatting is a thing not possible to the average European. A Japanese kneels down, then quietly bending his knees sits on his feet, the toes being extended straight backwards. Let any of your readers try the attitude, and report the result. The writer's attempts resulted in the most lamentable failure. Of course a worker sitting as described requires a very low table only; indeed, his work-bench is more like a very low stool than any other European article of furniture that I know of.

Farsari's artists were very slow and careful in their work. He informed me that he was satisfied if each coloured two or three prints in a day. This allows time enough for each print to be really well coloured, and, indeed, I have seen no better work in the way of coloured photographs anywhere than some of Farsari's productions. There is, at least, one dealer in photographic requisites in Yokohama. There is also, at least, one Japanese plate maker. I have not yet been able to judge of the quality of the plates he turns out, but hope soon to do so.

Chemicals are to be had at very moderate rates, and of guaranteed purity. I mean actually guaranteed by the Government, which allows no chemicals to be sold till they have been examined at the Government laboratory, have proved to be of a high standard of purity, and have been stamped with a Government stamp, indicating that the examination has been made. This applies, at any rate, to all chemicals that may be used as drugs, and, therefore, applies to most of those used in photography, and others also, I believe; but of this latter I am not certain. The examination, I understand, is no perfunctory affair, but is a very genuine one. Might not some countries, whose people imagine that they are far more civilised than the Japanese, take a hint in this matter?

Of the amateur element there seems to be scarcely anything in Japan at present. Many amateurs have visited the country, and have exposed plates in it; but of residents there are, at present, so far as I know, only some three or four, including myself, who practice photography as an amusement.

At the College of Engineering, photography is more or less used for scientific purposes, apparently the wet process only being worked. The "blue process" is used for copying tracings.

It will soon be holiday time with me, and I intend, when it is, to take a small camera with me right into the interior. I shall endeavour to get to places where no "white man" has yet been; although I am by no means confident of being able so to do, as there are now but few such places left. At any rate, I am pretty sure to meet with some things of interest enough to be worth communicating to British readers, and I may possibly be fortunate enough to get some pictures which may be different enough from anything we have at home to be worthy of reproduction. This, however, remains to be seen. I intend to take with me only a camera, two lenses, and about half a gross of plates. The mode of travelling is by "jinrikisha," a jinrikisha being a small two-wheeled carriage drawn by a man. The hire for carriage and man is only some 2s. 6d. a-day in the country; of course the weight that can be carried is limited, although it is extraordinary what burdens a good jinrikisha man can carry, at what rates, and for how great a distance. On flat ground a good runner will keep up a rate of eight to nine miles an hour for several hours, and show scarcely any signs of distress at the end of that time.

W. K. BURTON.

ON EXPOSURE.

EXPOSURE, it need scarcely be said, means the act of submitting a sensitive surface to the action of the light sufficiently long to obtain a developable image by accepted and ordinary methods. This is the broad

way of looking at it, for, at present, it is an undecided point how long it is necessary for light to act before this developable image is produced. More than one eminent scientist believes that the *most* instantaneous impact of light under any circumstances (that is, strong or weak light) is sufficient to produce that molecular condition that we discover to have taken place on development. In a communication I received from Professor Hunt, he said his opinion was that the mere momentary impact of light was sufficient to produce the requisite molecular alteration. It would therefore depend on the means used to develop this latent image that would determine the quality of the negative, under exposure being an obsolete term.

At the present time we unfortunately have to deal with many under exposed films, according to our knowledge of development, and although the image may probably be there, we have no means of making it available. A developer sufficiently potent has yet to be discovered, and till that time comes we can do little more than make the best use of those we have. Therefore, in talking of sufficient exposure, it must be understood to mean an exposure that can be developed into a good *printing* image, in contradistinction to an image that may look pretty as a negative and interesting as a chemical effect, and that by means of developers in ordinary use, such as alkaline pyro or ferrous oxalate. I believe most photographers look to ammonia as the most effective alkali for this purpose, although by some workers perfect results have been obtained with ferrous oxalate, and with the most brief exposures.

Hydrokinone, and other unusual developing agents, may for our purposes be disregarded for the simple reason ferrous oxalate and alkaline pyro are almost universally used. Much also depends on the emulsionised plates, and in the present state of affairs these are very variable, a somewhat loose style of estimating their rapidity being adopted, the assumed standard of so many times quicker than wet collodion being a popular style of description; a wet collodion film itself varies very much in rapidity, according to the manner of its preparation. Thirty, forty, fifty, or sixty times more rapid than wet collodion conveys but a very ambiguous idea of the rapidity of the plates so labelled. The Warnerke sensitometer is, perhaps, the best available guide, and is, under certain conditions, a very useful and reliable instrument. The plates in many instances do not carry out the legends of rapidity inscribed on their wrapper, whatever means may have been used to estimate them.

There are in existence many examples of what is termed instantaneous photography on wet collodion plates—street scenes with moving figures *sharply* depicted. It must be borne in mind street scenes, in large towns and cities, are much more weakly lighted than seaside views, and to render such sharply indicates a very sensitive film. To judge by the recent attempts of street work with presumably the quickest plates in the market, the assumed fifty or sixty times rapidity is very questionable indeed. With a wet collodion plate years ago, the exposure of a portrait in a good light at the seaside averaged about half a second, stops $\frac{1}{4}$ or $\frac{1}{5}$, everything being in good order and working at its best. With an acid bath and some samples of collodion, five to ten seconds, and even longer with a similar light and stop was not too much. So it will be seen that from any point of view wet collodion can scarcely be used as a standard, *unless the time required for the exposure of the collodion and the aperture of lens used is stated*. We will put it this way—an interior would be properly exposed in half an hour with wet collodion; now if there is the slightest reliance to be placed on the statement that the dry plate is sixty times faster, *half a minute* ought to be sufficient to produce a similar *well exposed negative*. For my own part I have never met with a plate that would produce as good a negative as that given by the wet collodion in half an hour in less than fifteen or twenty minutes. And I look on these statements of rapidity as most misleading, not to say ridiculous. Some effect would no doubt be produced by the short exposure, and the high lights might be indicated, but something more than this is required for a good photograph. It seems as if *only* in a brilliant light a gelatine plate works very much more rapidly than a collodion one, but where there are great contrasts, as in interiors, the difference is not nearly so great; in all probability an exposure that would have no effect on a wet collodion plate would show the windows of an interior distinctly, but the dark portions would not be rendered any better than on the wet plate, or, in other words, they would not be impressed at all.

There is yet much to be learnt as to the behaviour of gelatine plates, and the infinite variety of "makes" tends to complicate matters. The same emulsion formula will give vastly different results dependent on the manner of mixing, both in quality and rapidity, and the test standard for it varies greatly, as I have already pointed out. Under these conditions uniformity of result cannot be expected, nor can exposures be regulated with anything like certainty.

No means should be neglected to obtain uniformity, both in making the emulsion and developing. The first is, perhaps, out of the power of most photographers, who are dependent on commercial samples of dry plates; but the latter is more under their control, and a good style of development well stuck to will be much more likely to produce good results than the trial sometimes of one kind and sometimes of another. The characteristics of dry plates necessarily vary, and perhaps contrast with wet collodion and gelatine in the effects of prolonged exposure as much as anything.

The reversal of the image produced by excessive action of light is very curious. With wet plates it would simply produce dense fog, but with gelatine a point is reached where, instead of fog and density, the image gradually changes its character from a negative to a positive. Some plates are very much more prone to this than others, and where the balance is very delicate the plates are usually very difficult to manage, being apt to give an image deficient in pluck, or, in other words, work thin. Another peculiarity in some gelatine films is that—we will suppose a proper exposure effected, by continuing the exposure instead of the image reversing as in the previous case—it will continue to gain in intensity without getting any more detail, the shadows remaining as clear as if only the correct exposure had been given. Plates that give extra density in this manner are difficult to reduce by the ordinary means, hydrochloric acid and alum having very little effect. There also seems to be a tendency to want of gradation in all views that are very brightly lighted, say by full sunshine, whether interior or open landscape. This hardness is very much more pronounced in character than a similar effect produced on wet collodion, owing, I think, to the superior printing qualities of the shadows on wet collodion negatives to those of gelatine. Perhaps the difference in the physical qualities of the film may account for it, one being hard and thin and the other soft and thick. But whatever the cause, the effect is very decided, the advantage certainly lying with the wet plate, which will produce a softer and more delicate silver print.

It is a difficult matter to accurately gauge the printing qualities of a gelatine negative, but generally one that is *not quite clear* in the shadows gives the best results in most cases, although it looks worse as a negative than a clear, bright one. A wet collodion negative was usually condemned if there was *not* some little deposit or veiling over the whole subject. The veil in collodion was much more easily penetrated by the light than *apparently* the same amount of veil in a gelatine film, which in the case of gelatine will produce *flatness* in lieu of softness—a fault that has probably influenced photographers to so strongly advocate clear shadows in gelatine work, thus encouraging the fault of want of atmosphere that a slight trace of veil certainly gives, *providing it has the proper character*. It is necessary to make this reservation, as the veils differ as much in character as the plates and development; but given the right sort of veil there is no doubt of its usefulness. Very skilful photographers of artistic ability like plates that give a little green fog on account of this softening effect, but if the gelatine films were ideally perfect, the films themselves being absolutely clear except where acted upon by light and of the utmost sensitiveness, the image would be probably graduated, and the effect similar to a first-rate wet plate. This is the standard we must work up to in both emulsions and development. It is an accepted fact that an under exposed negative will not produce as good a print as a correctly exposed one. There is invariably a want of printing power in the detail of the shadows.

A fault very conspicuous in much dry plate work is that of want of atmosphere. Aerial perspective was easily obtained by wet collodion, and conferred upon negatives one of their greatest charms, for in a good wet collodion negative there was no part that ought to have it without *printable* detail; clear glass, or its equivalent, was only to be found in minute quantities in the very deepest shades. Light passing through such a negative met with a certain amount of resistance in all parts; and when we notice how much effect is produced on sensitised albumen paper by anything, even by clear glass interposing between the paper and the light, it can be easily conceived why the old wet plate gave such a soft, rich image, and that dry plates frequently fail to do so. The characteristic failing of dry plates is either to be flat in the shadows or clear and destitute of printing detail—merely another sort of flatness. Exaggerated density in the most brightly lighted portions of a picture of either interior or landscape is often experienced when the rest of the subject has had apparently the right exposure. This is a very annoying defect, and most difficult to deal with. It is to be hoped after a time the relation of exposure to development will be better understood, and we shall gradually eliminate the faults that crop up unexpectedly and give a vast amount of trouble.

These are but stray thoughts on the matter, as I feel myself far from thoroughly acquainted with the mysteries of dry plates, and a

proper exposure and development is with me, perhaps, as much a matter of guesswork as absolute and certain knowledge of cause and effect, and it seems probable that until experience sets matters right it will remain so. With regard to exposure tables—given an even, good light of the same intensity for all subjects, such tables would be exceedingly useful; but as we have to deal with light constantly varying, even when it appears uniform, their usefulness can be but limited, and the proper time of exposure, even without any other complication in the form of plates and developers, must ever be a matter of experience, until that happy time arrives when photography will equal arithmetic in results worked according to rule.

EDWARD DUNMORE.

THE NEW OPTICAL GLASS AND ITS IMPORTANCE IN PHOTOGRAPHY.

THE reader has undoubtedly heard or read a descriptive notice of the new German optical glass and its wonderful properties. More than enough has been published, in various periodicals, by more or less competent writers, of this certainly very important matter, without giving the public a true understanding of the characteristic features of this invention or discovery. It may, therefore, be welcome to all who take an interest in the matter to learn a little more about it from one who has been for half his lifetime engaged in the production of articles and instruments for which the so-called optical glass serves as a material.

Thanks to the progressive and industrious spirit of our age, there are at present in general use a large variety of optical instruments and lenses, serving the most varied scientific, business, and private purposes. Almost every one of them, from the large and costly astronomical telescope down to the modest pocket spy-glass, are, in these exacting times, required to be "achromatic"—which means "free from colour." An achromatic glass frees the object, or, rather, the image or picture of the same, from the disturbing prismatic or rainbow colours with which the edges are fringed when seen through a simple non-achromatic glass. Let us see how this is accomplished.

The magnifying, or reducing, or image or picture-producing lens owes its peculiar attribute to the property possessed by the glass of which it is constructed to change the direction of a ray of light, when it enters the lens, in an oblique direction to the surface at which it entered. This property is called "refractive power;" it varies not only for different kinds of glass—that is, one glass will, under equal conditions, refract the light to a greater angle than another—but it is also in one and the same glass different for the different components of the ordinary white light, and consequently a ray of white light, if refracted by passing a prismatic glass, will separate and disperse its components, which then present themselves to our eye by their own specific colour by which we recognise or distinguish each of them. These colours are the well-known prismatic or rainbow colours, and the power of the glass to separate these components or colours is called "dispersive power." Flint glass has a much greater dispersive power than crown glass. Its refractive power is also greater than that of the latter, but the relative difference of the dispersive powers of these two glasses is much greater than that of their refractive powers. Therefore, if an ordinary crown-glass lens be combined with a negative (reducing) flint-glass lens of just enough (negative) dispersive power to neutralise that of the crown-glass lens then its negative refractive power will not be great enough to completely neutralise that of the crown-glass lens, and consequently there will be a remainder of refractive power forming a focus of greater length than that of the crown glass alone without the flint glass. But, as the prismatic colours by this combination are completely neutralised, the remaining refraction is free from colour dispersion. This is an achromatic lens.

If a crown-glass prism, of such angular form as to have a great refractive power, be placed at some distance before a white screen, so that a beam of sunlight passing through the prism will be horizontally dispersed to a widespread colour spectrum upon the screen, and if right above or below this a flint-glass prism be placed which is of so much smaller angle (because of the greater dispersive power of the glass) that the spectrum produced by it appears to be just equal in length to that of the crown glass; if, then, by moving one or the other prism, the spectra are so adjusted that one appears exactly below the other, it will be presumed that all the corresponding colours of the spectra coincide so perfectly as to make the whole appear like a single spectrum of double width; and such coincidence is, indeed, highly desirable, because it is the condition of perfect achromatism. But, unfortunately, such is not the case, for, while the total or general length of the two spectra are so adjusted as to be equal, the corresponding colours of the same cannot be made to be all in line at the same time;

for instance, some of the colours of the upper spectrum will appear a little too far to the right, and others a little too far to the left. There is, indeed, a marked difference between the two spectra in the relative widths of their corresponding colours, and this difference is so great as to permit only two of the bands of colours to be in line at the same time, thus making the perfect coincidence of the spectra impossible. For this reason it is easy to understand that the achromatism of a lens, composed of such crown and flint glass, cannot be perfect, but a small remnant of all the colours but two will be visible, even with the most favourable proportions in the combination of glasses. This remnant of colour is called the "secondary spectrum."

As, therefore, owing to the described unfortunate fact, it is really impossible to get, by means of the combination of crown and flint glass, more than two of the spectral colours to coincide, or, in the case of a lens, to unite to a common focus, the question now arises, which two colours of the whole spectrum should be united to give the most favourable results? This question is answered, theoretically, by calculation, as well as by practical experience, thus: That the orange-red and bluish-green which enclose the brightest and strongest visual colour, the yellow, are the most favourable to be united to a common focus, and, indeed, a lens corrected in this way produces a very brilliant and colourless, or rather, colour-correct image of the object. This mode of correction is therefore most generally adopted by opticians and mathematicians in the calculations of their optical formulæ.

But for photographic purposes an objective of this correction has the fault that the strongest chemical or actinic colours, the indigo and the violet, have a longer focus than the brightest visual colour, the yellow, and, in consequence, if with such an objective the image of an object is sharply focussed by the eye, the photographic picture produced in the same plane will appear to be out of focus, and in order to obtain the desired sharpness of the latter the lens must, after focussing by the eye, be drawn out to a certain—or rather uncertain—point before making the exposure. To obviate this difficulty, caused by the difference of the visual and actinic foci, the mode of correction must be changed in such a manner that the brightest visual, the yellow, and the strongest "actinic" colour, the violet, are united to a common focus. By this mode of correction the photographic picture will come out sharp, when properly focussed by the eye, and the objective thus corrected can be said to be free from difference of the visual and actinic foci.

From these explanations* it appears that the secondary spectrum is the principal cause of a number of defects in the correction of our present achromatic lenses, and that this is especially so in reference to the photographic objective. If the spectra of the two glasses used in the construction of the objective were perfectly coincident then the latter, if properly corrected, would unite all the colours of the spectrum to a common focus, and the secondary spectrum would be an unknown phenomenon, and consequently not only the visual and actinic foci would be perfectly identical, but also the whole amount of light passing through the objective would form a common, sharp focus, and an increased rapidity, aside from perfect sharpness of the picture, would be the result. But, as has been stated before, the secondary spectrum permits only two colours to be united to a common focus, and although the two colours most favourable to photography are selected, the rest of the spectrum is not only lost for co-activity in the production of the picture, but, because of its being more or less out of focus, is even injurious to the same. Since the discovery of the secondary spectrum as the cause of the remnant of colour noticed even in the most carefully corrected objectives, various attempts have been made from time to time to produce two kinds of glass which would, besides the other requirements of an achromatic lens, produce coincident spectra, or nearly so—that is, nearer than the present crown and flint glasses do.

About twelve years ago the writer of this received intelligence that an English firm had succeeded in producing crown and flint glass, which, if used together for an achromatic lens, would leave no secondary spectrum. Samples of this new glass were ordered, but the order was never filled. Later on it was reported that one of the first opticians of England had done his utmost to construct from this glass a telescope objective of superior quality, but had failed in his endeavour. And, furthermore, that it was exceedingly difficult to obtain a perfect polish on the surfaces of lenses made of the new glass, which, therefore, had to be regarded as a failure.

Some time ago Dr. Abbé, Professor of Mathematics at the University of Jena, Germany (who made himself famous as the scientific assistant of Dr. Carl Zeiss, the optician of the same place, in the improvement of the microscope), began experimenting to find some chemical composition to be used in the construction of crown and flint glass of such superior quality as to suit the advanced requirements of the present achromatic objectives, and at the same time to have such proportions

of their prismatic spectra as to reduce, or, if possible, to eliminate the secondary spectrum. He was assisted in his experiments by eminent chemists, and thus, by the co-operation of the mathematician, the chemist, and the optician, a success was soon reached and announced to the world. It was, however, admitted, at the same time, that considerable work and experimenting on a more extensive scale would yet be required to carry the important problem to a final and complete success, and the German Government generously appropriated the sum of ten thousand dollars to secure the great work as a benefit to the world. Thus patronised, the new Jena works for the production of optical glass at last offered to all opticians their new productions, furnishing full descriptions and a scientifically valuable table of their various glasses, from which in exact figures all their special optical properties and relations to each other can be learned. Thus the optician was enabled to select from the list just what was needed or preferred for his special work. The writer has since that time had sufficient experience with the new glass to feel competent to give a correct and reliable report regarding the value of the product as a superior material for the construction of optical instruments in general, and for photographic objectives specially.

The new glass does not completely remove or neutralise the secondary spectrum, and, indeed, the makers themselves do not claim this for it; but it unites three colours of the spectrum exactly to a common focus and brings the rest so near to this focus that only with great difficulty the trained eye can detect a very faint "tertiary spectrum." To one who has for many years treated optical glass in earnest endeavour to get the best possible achromatic lenses out of it an objective made of the new glass and carefully corrected, appears as a great phenomenon—a missing of something to which he had been so long accustomed that its presence seemed a natural necessity—a condition of the achromatism of a lens.

The great value of the new glass to photography could hardly have been given a more severe test than was done recently by means of a compound objective of three-quarter-inch equivalent focus, which was constructed of the new glass by the writer for the microscope only, without special regard to photographic purposes. It was, however, afterward tested photographically by Mr. George W. Rafter, of Rochester, N.Y., an authority in photo-micrography. The negative was taken at a distance of seven and a half feet from the objective, thus giving a magnification of 110 diameters.

By a close comparison the image on the ground plate could not be detected to be different in the slightest degree from that reproduced in the negative, showing conclusively that there was not the slightest difference of visual and actinic foci. According to Mr. Rafter's own statement, the lens is in fact a remarkably fine photographic objective, although not expressly made for that purpose. The new glass has a very clear and brilliant appearance, the crown glass being entirely free from the slightest trace of colour, and the flint glass being but very slightly tinted, is at least equal to the best in that respect. The prices of the new glasses, both flint and crowns, are high, being nearly eight times that of ordinary optical glass. ERNST GUNDLACH.

CONTROLLING THE TONES OF PHOTOGRAPHS BY DEVELOPERS.

The following formulæ are for use with gelatino-chloride paper or plates. The quantities are in each case calculated for one ounce, three parts of each of the following solutions being employed and added to one part of solution of protosulphate of iron; strength, 140 grains to the ounce.

Slaty Blue.

1.—One part of the above solution to three parts of a solution of citrate of ammonia.

Greenish Brown.

- | | |
|-----------------------------|-------------|
| 2.—Citric acid | 180 grains. |
| Carbonate of ammonia | 50 " |
| 3.—Citrate of ammonia | 250 grains. |
| Chloride of sodium | 2 " |
| 4.—Citrate of ammonia | 250 grains. |
| Chloride of sodium | 4 " |

Sepia-Brown.

- | | |
|-----------------------------|-------------|
| 5.—Citrate of ammonia | 250 grains. |
| Chloride of sodium | 8 " |

Clear Red-Brown.

- | | |

In the Photographic Exhibition at Florence, the firm of Corvan* places on view a frame containing twenty proofs produced by the foregoing twenty formulæ, in such a way that the observer can compare the value of each tone and select that which pleases him best.

—*Le Moniteur de la Photographie.*

IMAGE TRANSFERENCE.

By the term Image Transference, I propose to denote certain effects produced on sensitive films, effects curious in themselves, and of interest in connection with the subjects of papers which have appeared in the May and June numbers of this Journal.

In those investigations it was shown to be possible to take a film of a silver haloid—chloride, bromide, or iodide—and after making marks upon it with sodium hypophosphite to obtain a development of these marks, precisely as if they had been impressed by light, but quite in-

* Does this mean Mr. A. Cowan?—*Translator.*

dependently of any exposure to light. I now propose to show that it is possible to develop on a film of silver haloid a complete image—a print from a negative, for example, without either exposing the silver haloid to light, or to the action of hypophosphite, or subjecting it to any treatment whatever, between the moment of its formation and that of its development. The film of silver haloid comes into existence with the image already impressed upon it. For this purpose almost any silver salt is selected; citrate, benzoate, tartrate, pyrophosphate, &c., answer perfectly. (Some silver salts, the phosphate especially, undergo a slight reduction spontaneously in the dark; these are less suitable.) A film of the silver salt selected is formed on paper by the ordinary methods, and this is exposed under the negative to a few seconds of sunshine.

The next step is to convert this film into one of silver chloride or bromide by plunging it for a few minutes into dilute acid. Ordinary hydrochloric acid may be diluted with six times, commercial hydrobromic with two or three times, its bulk of water; the exact strength is unimportant. After a short immersion, the acid is to be washed out, and it only remains to put the film, now consisting of silver haloid, into a ferro-oxalate developer, when the image appears at once. The chloride or bromide of silver, into which the salts above mentioned are rapidly converted by the halogen acid, comes into existence with the image already impressed on it at the instant of its formation. So that although the substance which received the image is completely broken up and destroyed, the image is not, but is transferred in all its details to the new film of silver haloid.

It is therefore evident that the action of light on all silver salts that can thus transfer an image must be similar in all its essentials to the action of light on the silver haloids. An important conclusion follows, that all such silver salts must be capable of forming subsalts, else the image could not be transferred. In the case of most silver salts the existence of such subsalts has not before been recognised or even suspected; indeed, if I am not mistaken, the existence of such a subsalt of silver phosphate has been expressly denied. But the image formed by light on silver phosphate can be transferred, therefore subphosphate must exist.

These results have also a very direct bearing on the subject of one of my papers in the last number of this Journal. I there endeavoured to show that the photosalts of silver as obtained by purely chemical means are identical with the products of the action of light on the silver haloids, both with the material of the latent image and with the visible product of the continued action of light, or rather with the most characteristic constituent of that product. As respects this latter identity, I showed that although the brightly-coloured photochloride could not be obtained by the direct action of light on silver chloride, it could readily be formed indirectly by acting with light on other salts of silver, and treating the product with HCl. It might be argued that in this proof one link was wanting, namely, proof that the photochloride obtained by the action of HCl on silver salts other than chloride exposed to light was of the same nature as that obtained by the action of light directly on silver chloride. The results above described supply that link, if it was needed, and show that the photochloride obtained by the action of HCl on silver salts, other than the chloride exposed to light, has the same capacity for development as has the material of the latent image obtained on ordinary silver chloride.

But this proof itself may be thought liable to an objection. It may be said that as an image was certainly impressed upon the original film, it is not completely proved that the halogen acid had anything to do with the ultimate production of a developed image. The objection would not be well taken, and the experiment may be varied to two ways, either of which eliminates it.

Most silver salts are soluble in nitric acid. After applying the halogen acid, it may be washed off, and the paper may be placed in nitric acid until every trace of the original salt (supposing that any escaped the action of the HCl or HBr) is removed, and until it is absolutely certain that nothing is left in the film but the silver haloid. When this is done, the development, so far from being impeded, is rendered only the stronger and brighter. Certainly, therefore, the silver haloid is the essential base of the development.

Another very decisive experiment may be made in this way. Paper prepared with tartrate, oxalate, or almost any other salt of silver, is to be exposed for a minute or thereabouts to a strong light (not under a negative). It is then taken into a dark room, and marks are made upon it either with a glass rod or a camel-hair pencil dipped in dilute hydrochloric or hydrobromic acid. After letting the acid act for five or ten minutes, it is to be washed off, the paper plunged into nitric acid, and after again washing it can be placed in a developing solution, when the marks made will appear black on a white ground. This mode of operating gives a very convincing result. The nitric acid treatment may be omitted, but when this is done the number of salts that can be used is more limited. The four salts first above mentioned give good results, even without the nitric treatment, but some silver salts undergo a spontaneous change in the dark by keeping a short time, such that when they are placed in a developing solution (without exposure to light) they may blacken instantly all over. Silver tartrate is one of the best salts to operate with, though pyrophosphate, citrate, oxalate, and some others do almost equally well. Sulphate, antimonio-tartrate, phosphate, nitrite, and arsenite, do not give good results, except with the nitric acid treatment.

With a salt like tartrate or oxalate the experiment is very striking. The paper imbued with it is exposed to light over its whole surface, it is then taken to the dark room, and simply marked with dilute HCl or HBr and washed. Thrown into a developer, all the marks of the halogen acid quickly blacken, proving, first, that the effect of light is transferred from the one salt to the other; second, that the effect as transferred to the chloride or bromide is far more susceptible of development than it was in the original salt. It seems a not unreasonable explanation of this last mentioned fact that the greater sensitiveness of the haloid compounds may depend on their power to combine with their own subsalts, so that the reduction may commence with the subsalt, and quickly extend from it to the portion of normal salt with which it is combined; that, on the other hand, other silver salts may not share this power of uniting with their subsalts, and are consequently more slowly and imperfectly attacked by the developing solution. This explanation may or may not be correct, but seems not improbable.

A curious fact incidentally presented itself in the course of this investigation: that when paper prepared with silver salts, other than the haloids, was exposed to light, and then marked with HCl, the effect of a short exposure, so far as development was concerned, was as great as that of a long one. A piece of paper was prepared with a given salt by non-actinic light. It was then placed between the leaves of a closed book with one end projecting. The book was then placed in the light (very faint sunshine), and the prepared paper was gradually drawn out so that different portions received progressive exposures from four hundred seconds down to three seconds. A number of marks were made with HCl diluted, parallel to the end of the paper, so that to each mark corresponded a different exposure from three seconds to four hundred seconds. The papers were then placed in nitric acid, washed and developed. These pieces are before me as I write, and it is impossible to say by the appearances which portion received the three seconds, which the four hundred. The marks are equal in strength on each paper from one end to the other. The salts used were: Silver benzoate, tungstate, phosphate, pyrophosphate, and tartrate. The short exposure gave a sufficient basis for development, the longer effected nothing more.

The object of this series of papers has been to offer a new explanation of the nature of the latent photographic image, and to show that it consists neither of the normal silver haloid physically modified nor of a subsalt, but of a combination of normal salt and subsalt. That the subsalt loses in this way its weak resistance to reagents, and acquires stability, thus corresponding to the great stability of the latent image, which, though a reduction product, shows considerable resistance to even so powerful an oxidiser as nitric acid.

Further, that this combination of normal salt and subsalt, which constitutes the material of the latent image, can be obtained by chemical means, and wholly without the aid of light. That the forms of these photosalts, as I have ventured to name them, which correspond to the material of the latent image, are either colourless or nearly so, but that other forms, possessing beautiful and often intense colouration, also exist. With the chloride some of these brightly coloured forms show a ready tendency to reproduce colour, in some cases with well marked and beautiful tints. So that we have here an approach to the solution of the problem of obtaining images of objects in their natural colours from a quite new direction, and probably with better hopes of an eventual complete success than by any of the older methods.

—The American Journal of Science.

M. CAREY LEA.

BLEACHING BROMIDE PRINTS.

[American Convention.]

PREPARING sketches in lines with black ink for photo-engraving purposes is now so general that it has seemed to me there is a need, if possible, of using bromide paper as an aid to the artist for this purpose, since it would save time and be more convenient. It is well known that if an untuned silver print be inked over in lines, the photographic image may readily be bleached out by pouring on the surface a solution of bichloride of mercury and alcohol, or the print may be floated thereon.

To obtain the best effects by the photo-engraving process it is required that the original sketches be of large size; hence, when a picture is to be reproduced, it is necessary first to make a small negative, then a positive by contact, and thirdly, from that, to produce an enlarged negative, from which the silver print is made, over which the artist sketches. It occurred to me here was an unnecessary amount of time lost, provided we could utilise the bromide paper, for upon that we might enlarge directly from the original negative to any desired size; then, by sketching over with ink, our object would be attained. But the difficulty that presented itself was the simplest and best way to bleach out the photographic image on the bromide paper, so as to leave a white background between the ink lines.

In looking over several books on photography, I was unable to find a definite formula for this purpose, but recently I read that a picture on bromide paper was made to entirely disappear by the use of ferric chloride. Acting on this suggestion, I submitted a bromide print, after fixing and washing, to the action of a very strong solution of ferric chloride for many hours, with the result of bleaching it out until it attained

a sandy brown colour. Beyond this the solution had no further bleaching power. Using a solution of bichloride of mercury on another print I was able to whiten it, but the shadows were of too pronounced a brownish yellow colour to render it of any use.

Recently I have tried a series of experiments which may be of some interest, as showing by what simple means successful results may sometimes be obtained. I first made an 8 x 10 under-timed bromide print, and before fixing it in hypo cut it into four parts. Two of the parts I fixed in a mixed hypo and alum bath. The other parts I left unfixed. Knowing that a weak solution of ferrid-cyanide of potassium (commonly termed red prussiate of potash) in hyposulphite of soda was the standard solution advised for reducing negatives, I inferred that if it was made strong enough it might act as a good bleaching agent by reducing away the picture. Accordingly, I prepared the following solution:—

Water	6 ounces.
Hyposulphite of soda	480 grains.
Ferrid-cyanide of potassium	240 "

Dissolving each in the order named. The solution presented a dark green colour and kept clear for about an hour, after which it became muddy.

Laying one of the unfixed portions of the bromide print upon a plate of glass I poured over it the above solution; rapidly and in about a minute all traces of the picture at once disappeared. After washing, looking at it by white light, it was, as I surmised it might be, quite yellow. The next question was to dissolve out the extra silver unacted on by light and whiten it. So I immersed it in the hypo and alum bath; but this had the reverse effect, for by decomposing the ferrid-cyanide the paper rapidly changed to a beautiful Prussian blue colour. When the print was dried I afterwards endeavoured to eliminate the blue by immersing in a weak solution of carbonate of soda, but without success. I then subjected the fixed portion of the print to the same solution for three-quarters of an hour, but was unable to reduce away the picture sufficiently. The result of this experiment shows that an unfixed bromide image may be immediately bleached out with the same solution, leaving a yellow colour on the surface of the paper.

I next made a solution of bromide of copper as follows:—

Bromide of copper solution	$\frac{1}{2}$ ounce.
Water	3 ounces.

I then submitted an unfixed portion of the bromide print to its action. In the course of three or four minutes the image was transformed to a very light yellow sandy colour. At this stage I dipped my finger in the hypo solution, then touched one corner of the print, and noticed all trace of the picture to disappear at that point very quickly. I then inferred a mixture of hypo with the bromide of copper would effect the same result. In this I was not disappointed, and found the following solution would effectually and easily bleach out either an unfixed or fixed bromide print in about five minutes' time. Continual movement of the solution over the surface materially helped the bleaching action:—

Bromide of copper solution	$\frac{1}{2}$ ounce.
Hyposulphite of soda	100 grains.
Alcohol	1 ounce.
Water	2 ounces.

The alcohol is added to prevent the ink from spreading.

I purchased the bromide of copper solution already prepared, but it is very easily made. The following is the usual formula. Make two solutions as follows:—

Bromide of potassium	120 grains.
Water	4 ounces.
Sulphate of copper	120 grains.
Water	4 ounces.

Mix the two and we have a bluish bromide of copper solution.

A final experiment was the immersion of a bromide print for long intervals in two successive baths of boiling water.

To my surprise, though the test was severe, no dissolving action took place. By running the finger over the surface of the print, the soft gelatine could be felt, but the picture appeared to be imbedded in the texture of the paper and did not disappear.

With this paper I submit the specimen sheets or pieces of paper treated in the different ways described for examination. The experiments were made upon Eastman's A paper, developed with ferrous oxalate.

In respect to the finished polished print here submitted, my experience is that one of the best and easiest ways to secure a high polish is to employ what is known as hand-polished vulcanised rubber sheets, or specially prepared ferrotype plates, and also a paper coated with rather more than the usual amount of gelatine. Too little gelatine will give the surface of the print a mottled, half-finished appearance, particularly when observed by reflected light. In warm weather the prints will not readily strip from the rubber sheets, unless they are fixed in a combined hypo and alum bath. Before squeegeeing on to the rubber, the surface of the print should be rubbed over with the fingers under water in the tray, to take off any of the milky sediment settling upon it while fixing. If this precaution is not observed, the print, when stripped, will present a mottled, mealy appearance.

A very simple squeegee is a thick rubber tube about one inch in internal diameter, drawn over a round stick, made somewhat longer than the tube.

The print is laid face downwards on the rubber, the surplus water on the back being taken off with blotting paper, the roller squeegee is then rolled over the print, pressing out all air-bells, besides bringing the print in uniform contact with the rubber. When dry, it is readily pulled off from the rubber, having a fine polish. No talc or oil is necessary. I have used these rubber sheets for nearly two years with perfect success, and do not notice that the surface becomes dimmed. For giving a high polish to unmounted silver prints the polished rubber is unequalled. Simply squeegee the albumen prints while wet on to the rubber the same as the bromides.

In conclusion, I may add that many of our valuable processes are founded on simple experiments carefully carried out; if, then, all those photographers who have the time and inclination would study and experiment, note the results, and freely impart the same to others, how much richer in useful and practical information the entire fraternity would become. I trust scientific experimentalists in photography will become more numerous in future years, especially in this country, and that a spirit of intercommunication of ideas and the exchange of the results of practical manipulation, will override all feelings of hesitation, competition, and jealousy.

F. C. BEACH.

RAPID PHOTOGRAPHY.

A GERMAN photographer, Herr Ottomar Anschütz, of Lissa, is at present exhibiting in Berlin a new apparatus, constructed to the order of the Prussian War Minister, by means of which he is able to reproduce on a screen pictures of moving objects. The art of photographing moving objects in successive positions is not new, but Herr Anschütz has brought it to a state of perfection not hitherto attained. One of the earliest workers in this direction was the painter Lugardon, of Geneva, who succeeded in photographing sea-gulls; and later, the French *savant*, M. Marey, constructed his photographic rifle, by which it was possible to take in rapid succession twelve impressions of a bird at which the rifle was aimed while on the wing. By releasing the trigger twelve plates were in succession exposed for a fraction of a second, and thus photographs of twelve successive positions of the bird were obtained. But in all these attempts the time required to obtain an impression on the sensitised plates was comparatively long, the average being about one-hundredth part of a second, whereas Herr Anschütz has succeeded in preparing plates so sensitive that an exposure of one-five-thousandth of a second is sufficient. The experiments connected with these improvements were begun in 1882, and were carried out by Herr Anschütz with a large number of animals kept in a small zoological garden attached to his photographic establishment. He began by photographing troops whilst performing evolutions, and large masses of people assembled on occasions of historic importance; progressing then to the photography of animals, such as pigeons, storks, horses, wolves, and stags. In all, 1300 of these photographs have been taken by him up to the present.

By order of the Prussian War Minister, photographs were also taken at the military riding school in Hanover, the pictures produced being found of great value in equestrian instruction. The apparatus used contained twenty-four lenses, with exceedingly rapid exposure, so that the leap of a horse could be subdivided into twenty-four positions, the apparatus being perfectly automatic, and so rapid in action that all the twenty-four impressions were, in certain cases, received in $\frac{1}{72}$ of a second.

So far, the work above described has only reference to the subdivision of motion into component positions; but Herr Anschütz has also succeeded in constructing an apparatus by means of which he is able to again combine the pictures obtained in rapid photography and reproduce them on a screen, so as to show a large audience the actual motion of the object which was photographed. In principle, the apparatus is similar to the well-known optical toy, where a series of pictures rapidly revolving produces the illusion of actual movement, but the details of the appliance have been greatly improved.

The rapidity with which the pictures must be taken necessitates the employment of a small lens, and hence the photographs are very small, generally only seven-sixteenths of an inch in length and breadth. These are enlarged to one and three-quarter inch, and transferred to thin glass plates. The twenty-four transparent pictures thus obtained are mounted upon an iron disc containing twenty-four windows near its circumference for their reception, and this disc is rapidly revolved before a Geissler tube bent into a spiral. Four Bunsen elements and a large induction coil supply the necessary high-tension current to render the tube luminous. Between the disc and the Geissler tube is placed a ground-glass shade, in order to tone down the light, and the beam is thrown through an aperture upon a large screen, so as to render the picture of the object photographed on the glass plates visible to a large audience. The disc is revolved at a speed corresponding to that during which the twenty-four photographs were taken. In the case of the horse above referred to, this speed would be about eighty-five revolutions per minute. The usual make and break of the induction coil is replaced by a make and break arrangement worked from the spindle on which the disc is mounted, and the contacts are so arranged that the primary circuit is broken at the moment when a picture comes opposite the Geissler tube, and again established during the intervening time. In this way only one very brilliant induction spark passes through the Geissler tube at the moment the primary circuit is broken, and as the reproduction of the picture on the screen lasts only an

infinitesimal fraction of a second, it is exceedingly sharp. Since the successive pictures pass at the rate of thirty-three per second, the impression upon the observer is, however, practically continuous, and forms a faithful reproduction of the actual object as seen in motion.

—Industries.

ENAMELLING PHOTOGRAPHS AND OTHER PRINTS.

"My invention," says Joseph P. Phelps, of Muscatine, Iowa, in his specification, "relates to the transparent covering of photographs or other prints so as to secure a permanent glossy appearance, and also to securing required colour or tone of the picture after it is made, and it consists in the preparation, combination, and application of the ingredients hereinafter named and described, so as to produce the desired results with certainty and expedition.

"To enable others skilled in the art to make and use my invention, I proceed to explain the method of preparing and applying the different elements.

"I mount the prints to be enamelled on wet cardboard with common paste. I then prepare my emulsion in the following manner:—Glutina alba (or white glue), three ounces; soft water, eight ounces; half the white of one egg; glycerine, ten drops; French chalk, three grains. Put this mixture over a fire until thoroughly dissolved. Then take a French plate glass, or any finely polished glass, about two inches smaller than the cardboard the prints are mounted on (but large enough to cover the prints), which has been previously coated with the following solution:—Ether, one ounce; alcohol, one ounce; gun cotton, six grains; French chalk, one grain. I use to tint this last above solution any colour, so as to produce any desired tone on enamelled pictures, a drop at a time of the following preparation of 'fuchsine,' of any colour desired, mixed:—Fuchsine, one quarter ounce; alcohol, four ounces. Now lay this glass, coated side up, upon a block or raised surface inside of a tray made to catch the emulsion which runs off of the plate. After filtering the emulsion through a porous cloth into a pouring vessel of some kind, I pour a sufficient quantity across one end of the glass to cover the picture when squeezed over it. I then take the mounted print, clamp one end by a spring attached to the same block or platform that holds the glass, arranged so that the picture to be enamelled and glass with the coating of (No. 2) solution are exactly on a level. I now take a roller covered with thin rubber, or any material that will give slightly, and with one sweep roll the picture down on to the glass. I then lay the glass with picture on face down to dry. When thoroughly dry, run the edge of a knife between the edge of the glass and the picture, and the print will snap from the glass elegantly enamelled.

"What I claim, and desire to secure by Letters Patent, is:—1. An emulsion for photographs and other prints, consisting of glutina alba, soft water, albumen, glycerine, and French chalk, in about to proportions set forth. 2. An enamelling and tinting or toning composition, consisting of ether, alcohol, gun cotton, French chalk, and fuchsine, in about the proportions set forth. 3. The herein-described method of enamelling photographs of other prints, consisting in placing the enamelling emulsion in a line across a smooth surface, then clamping one end of the photograph or print, face down, to the surface over or back of the body of emulsion, and rolling the print upon the surface by means of a roller, substantially as set forth. In testimony whereof I affix my signature in presence of two witnesses."

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

LAST Thursday night, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. A. Haddon presided.

Mr. BUCHANAN WOLLASTON exhibited prints of negatives taken during the excursions of the Convention in Scotland. He also exhibited excellent instantaneous views of Dover Harbour, including some photographs of the "Calais-Douvres" and of other Channel-passage boats under steam. One of the Scotch views taken on board a steamboat contained a good likeness of Mr. Smith, the Hon. Secretary to the North London Photographic Society, while Mr. Smith was in mid air, taking a leapfrog jump over somebody else on deck. The exhibitor said that the diaphragmatic shutter was used. He should be happy to take platinum prints from some of the negatives and to present the prints to the Association. Could anyone recommend a good finder? He had tried several but was not altogether satisfied with the action of any of them.

The Hon. SECRETARY said that McKellen's was useful.

Mr. J. B. SPURGE recommended a biconcave lens.

Mr. A. COWAN added that a biconcave lens fitted on the middle of the top of

the front of the camera was good; a piece of brass with eyehole should be on the back of the camera, and the lens should have cross lines ruled on it. Everything necessary could be seen in the lens, even in sunshine, without any focussing cloth or screen over the arrangement.

Mr. A. L. HENDERSON said that a sixpenny Galilean telescope could be bought and the lens taken out for the purpose.

Mr. W. H. HARRISON called attention to a fine print in the *Bulletin Belge* from one of the Brussels prize negatives of M. Georges Wilmette, a Liège amateur; it had been printed phototype fashion by Herr. F. Bruckmann, of Munich, who was said by Mr. Léon Vidal to be one of the most expert men in Europe at that class of work.

Several members remarked that the women in the picture were represented at work left-handed; the sides of the photograph had apparently been reversed in the printing.

Mr. William England exhibited a photograph of Mr. Whiteley's establishment, taken a few days before it was burnt down. He also exhibited some views he had taken at Pangbourne while out with an excursion of the Camera Club.

Mr. A. P. Higgins exhibited some pinhole photographs.

Mr. W. E. DEBENHAM said that some very decent pinhole photographs had recently been published in *La Nature*, of Paris.

The CHAIRMAN remarked that spectacle lenses would, when stopped down judiciously, give photographs nearly as good as those obtainable with doublets.

Mr. HARRISON asked if good lantern pictures could be obtained from paper negatives.

Mr. J. B. B. WELLINGTON had never seen one so taken which was good.

Mr. F. A. BRIDGE had seen six very good ones taken by Mr. England upon Eastman's paper, not stripping films; the negatives were about half-plate size.

Mr. W. M. ASHMAN said that the pictures just mentioned bore projection upon a twenty feet disc.

Mr. ENGLAND remarked that their grain showed a little on the screen, but not offensively.

The HON. SECRETARY said that telegrams of congratulation had been sent from that Association and from the Convention to the American Photographic Convention sitting at Chicago.

BIRKENHEAD PHOTOGRAPHIC ASSOCIATION.

THE ordinary meeting of the above was held in the Free Public Library on Thursday evening, the 11th instant.—The President, Mr. J. A. Forrest, in the chair.

Owing to the hot weather and a number of members being on their holidays, the attendance was but small.

The Secretary exhibited a number of Muybridge's latest specimens of instantaneous photography, kindly lent for the occasion by Mr. J. J. Atkinson, of Manchester-street, Liverpool, which excited great interest, representing horses taken at racing speed, male and female figures, draped and nude, running, walking, jumping, &c. The action of the limbs as shown by the photographs quite upsets one's preconceived ideas of how they should be placed, and they are therefore of especial value to artists endowed with sufficient courage to depart from the conventional mode of depicting animals and figures in motion. Each plate had from twenty-four to thirty-six representations of the same figure, rendering it a simple matter to follow out the complete action of the limbs in running, jumping, &c., as the case might be; this is especially so when observed through the zoetrope, the figures and animals having then all the reality of life. Some thirty-six cameras are necessary to make a complete series—that is twelve of each of the three positions depicted, namely, front, back, and side views. The exposures are stated to have been the one-eight-hundredth part of a second, yet, rapid as this is, a wonderful amount of detail had been secured, speaking well for the actinism of the light in America, the same in England probably only giving a silhouette of the subject. To avoid vibration, the shutters are said to be quite detached from the cameras, and are fired by the object breaking fine threads across its path. Those interested in instantaneous work will shortly have an opportunity of hearing all about it *in extenso*, Mr. Muybridge being shortly expected in England.

The new Secret or Buttonhole Camera was also exhibited, and a developed plate with the six views it is capable of taking without being changed. They showed good definition, and rapidly moving objects were quite sharp. As was pointed out, there being no swing-back arrangement, the camera requires to be held quite perpendicular, or the lines of buildings, &c., will not be rectilinear. The conundrum of how this was to be remedied by an operator with an abnormal corporation was left unsolved, as was also the one of how to secure a developer which would exactly suit each exposure of the six on the plate.

Mr. E. Newall exhibited some interiors of a theatre by Messrs. Banks, Manchester, taken by the ordinary footlights and those at the wings. They showed good definition all over, and one, an imitation of a Turkish street scene, was most natural.

A member seeking the solution of a knotty point from the Chairman, gave rise to the advisability of having a question box; it was felt that novices might not always like a betrayal of their ignorance before the Society; and, on the proposal of the Secretary, it was agreed to that one be provided, and in future be on the table for the use of members, who are invited to use it freely, much information being often derived from discussing the failures of others.

The PRESIDENT showed a number of views he had taken at Ingleton and Vryny; the latter is the place where the Liverpool Corporation are, at immense cost, making their waterworks which are to supply the city. He stated that it was proposed to make a selection from these and others, with the object of having them bound with a *précis* sketch of the place and works, the whole forming an interesting *souvenir* for those interested in the place.

CARDIFF AMATEUR PHOTOGRAPHIC SOCIETY.

THE ordinary monthly meeting of the above Society was held on the 12th instant.—The President, Mr. S. W. Allen, in the chair.

The members were deeply interested in a demonstration given by Mr. H. J. Ord, of the Camera Club, on the *Eastman Stripping Film*.

He said:—For the development of these films I find the soda and potash developer to be the best, though I have seen some negatives developed with ammonia as good as the best developed with soda. The formula which I find best is the one recommended by Mr. Wollaston at the Convention held last month at Glasgow, namely:—

No. 1.

Sodic sulphite	8 ounces.
Hot distilled water.....	40 "

When cold render slightly acid with citric acid, add one ounce of pyro, and filter.

No. 2.

Sodic carbonate (washing soda) pure	3 ounces.
Potash carbonate, pure	1 ounce.
Water	40 ounces.

Mix equal parts of 1 and 2 for normal exposures. The development must be carried beyond the density usual for glass plates, as you must remember that the paper, which is only translucent, is afterwards removed. While these are fixing and washing I shall first prepare the glass on which they are to be placed, and then give you a *resumé* of the process. The paper is first coated with a layer of soluble gelatine, that is, just ordinary gelatine, and when that is dry it is coated on the top of this gelatine with the emulsion, which is highly chromatised, that is, rendered insoluble by aid of a chromium salt. After development, while the negatives are washing, and they need little washing before stripping, as you must remember that we are going to remove the paper which contains most hypo and wash the film from the back with hot water, you prepare the glass to receive them by first coating it with a solution of indiarubber in benzole. This is to prevent the collodion from sticking to the glass, and need be only very thin; about one part of rubber to two hundred of benzole is quite sufficient. When this is dry the glass requires a coat of plain collodion on the top of the rubber, which is allowed to set, and then placed in a dish of clean water, and the solvents washed out. You must not allow it to set too much, or you will be troubled by the film leaving the glass before you want it to. When the solvents are all out, that is, when the plate does not appear to be greasy when taken out, it is ready for the film to be "laid" down on it. The plate is put in water, and the film floated over it face downwards in the same way as in carbon tissue. The two are brought into contact, removed from the water, and squeezed down hard. The plate, with the film attached, is then placed between dry blotting paper, and a weight placed on top of it. It is allowed to remain there for about fifteen minutes, when it is ready for stripping. To do this the plate is plunged in a bath of warm water about 120° to 150° Fahr., and in about two minutes, by rocking the dish gently, the paper will float off, when the film ought to be gently brushed with a camel-hair brush, and placed in a bath of cold water. This is the time to intensify or clear, if thought necessary. The next operation is to put on the skin: The plate is placed in a solution of glycerine and water, one to twenty, the skin submerged in this and allowed to soak until it is lined, floated over the negative, brought into contact, removed from the bath and squeezed down, when it is allowed to dry. When it is *perfectly dry* run a sharp knife round the edge and strip off; the indiarubber coating may now be removed by rubbing gently with the finger or a pad of cotton wool soaked in benzole. I shall end by giving a few general remarks. Before beginning to develop read the instructions carefully, and carry them out to the letter. Be in no hurry, but take plenty of time and think of each step before beginning it. And lastly, if you make failures, don't blame the film, but your own want of skill, and I am sure if you carry out the instructions you will not make failures but good negatives, and give up glass almost entirely, as I have.

Correspondence.

Correspondents should never write on both sides of the paper.

A NEW SEEKER.—DECORATION OF PLATINUM PRINTS.—AUTHENTIC NOTES ON DAGUERRE PROMISED FOR "THE BRITISH JOURNAL OF PHOTOGRAPHY."

I HAD occasion to pay a visit to M. Chevallier, optician, and I saw a very ingenious lens intended to do away with the finders placed upon cameras. In our days of instantaneous photography, when pocket, detective, automatic, and other similar apparatus come to light hourly, to get a shot upon a flying object is not above the intelligence of the happy owner of such a camera, but that the principal object be in its assigned place upon the negative is "*une autre paire de manches*," as is said in France. Many systems have been devised to show the fleeting objects to the operator so that he can seize the propitious moment to pull the trigger. I think that shown me by M. Chevallier is the simplest and cheapest I have hitherto seen. It consists of a piece of glass three-eighths of an inch thick in the form of a parallelogram, in height less than an inch; ground concave on one of its surfaces; more or less in depth according to the focus of the lens to be employed. This instrument shows when well chosen the exact resemblance of the objects produced by the lens in the camera. It is small, and convenient to carry in one's waistcoat pocket; it is enclosed in a thin brass frame; and can be fixed, either upright or sideways, to the camera at a moment's notice.

One of our leading photographers is having a certain success by printing his proofs in platinum and having them tastefully decorated in water colours. M. Reutlinger (that is his name) has a very pretty exhibit on the Boulevard Montmartre, which attracts legitimate attention and admiration.

Thanks to M. Nadar and other gentlemen, I have been able to collect the portraits of the old French Masters and other interesting documents for the history of our art. In making inquiries, &c., for this purpose I

came across a gentleman, M. Nicolas Glaise, who writes me: "I have not the portrait of the tomb of Daguerre, erected in the cemetery of Bry-sur-Marne, which you desire; but I will return to that village to oblige you, and take a drawing of the monument, which I will send you on. Whenever any one occupies himself with that great artist, a personal friend of my father, I receive a double pleasure." This gentleman showed me a volume of the *Life of Daguerre*, in which were manuscript notes on the inventor of photography which have never been offered to the public. These notes I found so interesting that I solicited permission to translate and publish them in THE BRITISH JOURNAL OF PHOTOGRAPHY. This prayer was granted. Next week I will send them on to my readers.

59, Rue des Batignolles.

PROF. E. STEEBING.

PRINTING FROM GREASED PAPER NEGATIVES.

To the Editors.

GENTLEMEN,—I have lately taken a number of photographs on negative paper which I have had some difficulty in printing when greased, either from the grease soiling the positive paper or from the silver attacking the negative.

This difficulty I have now quite overcome by using one of Pumphrey's transparent films. By placing it between the negative and the paper it affords perfect protection to both, and in no way lessens the brilliancy and clearness of the photograph. The negatives can perhaps be printed without the application of grease, but the operation is such a tedious one that it is well worth the while to grease freely.

I believe stripping films have lately been invented, but as the process is somewhat complicated I, for choice, prefer the greased negative printed as described. The method is perhaps already in use, but in case it might prove of assistance to amateurs like myself, I give you my experience should you care to publish it in your JOURNAL.

I see numerous discussions regarding the merits of Glass *versus* Paper, but there can be no question that the ultimate decision must be in favour of paper.—I am, yours, &c.,

R. B. GRAHAM, Colonel.

Glenista, Cheltenham, August 11, 1887.

[The specimens enclosed by Colonel Graham quite attest the excellence of the system adopted by him, while the detail is as good as if the prints had been obtained from glass negatives. *Apropos* of separating the negative from the sensitive paper, it may not be generally known that Mr. Fox Talbot, in the very earliest days of photography, suggested the insertion of one or more thicknesses of paper or other diaphanous body between negative and print, in order to soften excessive sharpness in such places or subjects in which it was not desired.—EDS.]

A DISPUTED POINT IN DEVELOPMENT.

To the Editors.

GENTLEMEN,—It has been frequently asserted that, if a plate be soaked in plain water previous to the application of the developer, as some makers of plates direct in their instructions, the result will be a considerable retarding of the development.

I have had reason on more than one occasion to doubt the accuracy of this assertion, and only recently have had two very marked instances in exact contradiction. The first, a plain bromide emulsion made by a slight modification of my ordinary formula, proved to be extremely slow in development, until it struck me to give the preliminary soaking in plain water before commencing to develop, when, as I quite expected, that operation was greatly expedited.

More remarkable still was another emulsion, also of my own make, and containing a comparatively large quantity of iodide. This absolutely refused to show the slightest trace of an image until several minutes in the developer; but upon soaking it first the picture came up much more rapidly, the rapidity increasing as the time of preliminary soaking was increased. It is worthy of note that iodide should have a greater slowing effect upon development than bromide.—I am, yours, &c., DELTA.

[Our correspondent is wholly inaccurate in his conclusions, more especially in regard to the iodide, as he may possibly be led to believe on perusing an Editorial in another column.—EDS.]

WHAT IS THE CAUSE OF HALATION?

To the Editors.

GENTLEMEN,—Under the above heading in your issue of August 5, 1887, I see my name handled pretty freely by our friend "Monitor." As I presume he was not at the meeting of the Liverpool Photographic Society when the discussion on paper *versus* glass took place, I may perhaps be allowed to correct one or two items as given in the summary of the proceedings.

I am reported to have said that the film had nothing to do with halation, whereas I believe it has a great deal to do with it. What I said was that the nature of the material on which the sensitive film was spread had little or nothing to do with it; the cause in all the specimens there showed was over exposure, and that if a negative was taken of, say a window, for the window itself, and given the proper exposure, halation would not exist. But in order to obtain the interior or darker positions

of the building the window had twenty or thirty times its proper exposure, and on development halation showed itself. I maintain that, as far as the halation of the window is concerned, it is a clear matter of over exposure, and the fault would be further aggravated by the thinness of the sensitive film. If the film was of good thickness and of a dense, creamy nature the defect would be less apparent, whether on glass or paper.

But friend "Monitor" says the difficulty is to give the proper exposure to the glass roof and well lighted parts as well as to the darker portions of the picture. I see the difficulty in another light, namely, how to develop a plate, one portion of which has had thirty times its proper exposure in comparison to the other parts with one and the same solution, so as to give one the idea that the plate had been equally exposed.

Again, I did not say that the same amount of minute detail could not be obtained in a paper negative; but I did say that the same amount of fine and delicate detail could not be printed from a paper negative. And I say further, that I have yet to see the paper negative that will produce as good a lantern transparency or enlargement as can be produced from a good negative on glass.

May I make a suggestion as to the alleged greater rapidity of paper? Might it not be caused by the more equal and greater rapidity with which it can be dried after coating, as I have found in my experience the more equal and rapid the film is dried the more rapid the resulting plate? I presume paper would be attacked in the drying process from both sides.—I am, yours, &c.,

RICHARD CROWE.

FIFTY SITTINGS FOR A PORTRAIT.

To the Editors.

GENTLEMEN,—Your footnote to the above headed lines in last week's issue allow me to answer in the following:—When you say that you know of innumerable instances where painters receive assistance in their work from photographs, so can this only mean that a certain class of painters do exist who use photographs as a resource in executing their work; this I never did deny, but I pointed out such work as an imitation without any value relative to art. When names are mentioned like Sir Thomas Lawrence and Sir J. Reynolds, as it was the case in Mr. R. Barrett's article in connection with "Fifty sittings," &c., I think the idea not wrong that the talk concerns work of real artistic merit; then the only question can be, is it possible to paint portraits of artistic quality, as represented by the paintings of those named artists, quicker and without recourse to so many sittings as formerly, nowadays, with the aid of photography? And that is what I deny. But this is the assertion made by Mr. R. Barrett, and which provoked me to ask in what way is this suggestion to be accomplished? An answer in this direction, with the necessary distinct practical advice, would, I am sure, gratify many artists and—Yours, &c.,

Liverpool, August 15, 1887.

A PAINTER.

To the Editors.

GENTLEMEN,—I cannot understand Mr. R. Barrett's silence regarding your correspondent's question, "In what way a portrait painter may avoid or shorten the sittings nowadays?" and can scarcely think it inability. If, however, he declines the challenge, I will be very happy to answer "A Painter."—I am, yours, &c.,

Richmond.

ONE WHO FINDS PHOTOGRAPHY A HELP.

To the Editors.

GENTLEMEN,—By Mr. R. Barrett's silence I conclude he is unable to answer the question put in your JOURNAL by "A Painter." Can it be another example of a man laying down a theory on a subject he does not understand? No true artist would condescend to use photography as a help, and if he did it would only lead him astray. Photography is photography, but art is art.—I am, yours, &c.,

St. John's Wood.

AN ARTIST.

To the Editors.

GENTLEMEN,—In your last issue I have been brought to task by one of your correspondents, "A Painter," for not having answered a question put by him in a former JOURNAL under the above title. This same having its origin in my contributions on *Colouring as Applied to Photography*. If not too late, I think, I can satisfactorily, as well as easily (although he assumes my silence was the result of inability), answer his question.

The cause of my not answering it at once was ill-health, not having been able to read my JOURNAL, and so not seeing the "correspondence" on the subject, in the first instance. I am sure you will believe me, when I say that I would not for a moment withhold any little information that I may possess from any of the readers of THE BRITISH JOURNAL OF PHOTOGRAPHY. I will now try to answer the letter of last week, as it embraces all the qualities of the former one.

The aids of photography to a portrait-painter are many, so I cannot see where the trouble of my finding an answer could come in. I do not speak on the subject with a patriarchal experience, but I have been, all the same, closely connected with it for over twenty years. In the first instance, I have found people going to have a large portrait painted suggest to the artist that they would like it after the style of a certain photograph which has been regarded as successful by all their friends. In such a case, this photograph can be turned to account by the artist, and both help him in the drawing as well as in the preserving of many

details that would otherwise demand a sitting. This is in the case of an independent artist who may have no connection whatever with photography, but one who does not altogether eschew it. Of course, there are many artists like "A Painter," who will not accept the assistance of photography, such as Sir Frederick Leighton, or Sir John Everett Millais, and such conspicuous ornaments of a noble art; but there are also many exceedingly good men, upon whom fortune has not smiled so kindly, who are obliged to humble their pride and accept photography willingly as a help.

This will be more easily understood when I ask the question, "How many people, going to have a portrait painted, go direct to an artist, and how many have it done through a photographer?" I think the numbers will show favourably for the photographer. Now in these cases there are a series of pictures taken and proofs submitted for approval. One is selected for colouring, that is, for the portrait in question. Here the artists steps in and makes a minute entry of the peculiarities of drawing, and colour, &c., which will very rarely take over fifteen to twenty minutes. A transparency will be made from the negative, and by the aid of a Sciopticon, or magic lantern, a very correct tracing can be made on the canvas (I presume all this is saving the time of the sitter, I know it takes the artist nothing like a third of the time of a sitting). The colours will then be laid in and the portrait brought very near completion before one sitting has been demanded. And I have known artists, *really good ones*, who have in most cases been able to retain the image of the original so successfully as scarcely to require a sitting at all. This somewhat bears out what I said in my articles on "Colouring as applied," &c., but need not dispense with sittings altogether. Indeed, I think there should always be a few sittings before calling the picture finished.

I will just give one more instance before going to other portions of your correspondent's letter. Her Majesty Queen Victoria has commissioned an artist to paint Westminster Abbey as it appeared on Jubilee Day during the ceremony. What did the artist do? Well, he called in the aid of photography. The only reason I can assign for his so doing is, that he wanted photography to help him for the necessary sittings which he never would have been able to procure. If these few examples be not sufficient, I will be very happy to enter further into the matter.

As my opinion has met with a contradiction from "A Painter," I hope you will forgive me if I take exception at a few of his remarks and theories. He says, "A painter is bound to study with his own eyes the forms in combination with the many different shades of colours, and the transparent individuality of the skin, &c., to obtain a resemblance of nature in his picture." I never intended to convey the idea that by the use of photography a blind man could paint a portrait. But I do say that the artist who can see will save his eyes a deal of trouble by its use. Of the "individuality of the skin" being "transparent," I do not feel disposed to offer an opinion. He also says: "All painting done in another way can only be an imitation." Up to date I have always looked upon painting as more or less the art of imitating nature in colour. The more perfect the imitation was to nature, marking the degree of skill possessed by the artist. I also strongly deny his assertion that photography cannot be improved by retouching. He compares it to taking "out all the strokes of the brush visible in a painting and making a very smooth surface all over, but surely spoiling the peculiarity of the original." This theory might teach one that in painting portraits the same treatment may be used in the case of such a face as H.R.H. the Prince of Wales, as on that of "the Deal Boatman." In painting, as in life, we have the smooth and the rough, and should know how to treat both. Some articles appeared on retouching in the JOURNAL some time ago in which the writer's views were moderately clearly stated, and I feel sure the writer of them will be able to justify them if needs be, as I am always ready to uphold the fact that photography is a considerable aid to the modern artist.—I am, yours, &c.,

REDMOND BARRETT.

London.

BACKING PLATES.

To the Editors.

GENTLEMEN,—Some time ago I made a cement for microscopy, consisting of asphaltum dissolved in burning naphtha, but it did not answer for that purpose, so put it on one side. It answers, however, capitally as a backing for plates, being easily applied, quickly drying, and easily removable. I do not put it all over the plate, but only upon the upper half, and do not remove it until after development. Its presence does not affect the development in the least.

I take the bottom off a grooved negative box, allow the box to rest on two pieces of wood inside a large box with a lid, which is not closed down, the backed plates are put inside the grooved box, and the whole covered with a carriage rug; this arrangement allows of the plates properly drying, and can be performed by any amateur who possesses a dark room or cellar without any risk of fogging the plates.

The proportion of asphaltum to the mineral—not wood—naphtha is about one in six, and I like it better than Brunswick black, which will do, however.

My justification in troubling you is, that this communication may be serviceable to some of your readers.—I am, yours, &c., C. F. JARVIS.

Handsworth, August 17.

EXPOSURE TABLES.

To the Editors.

GENTLEMEN,—By the articles contained in the last few weeks' editions of your excellent JOURNAL, it appears to me that the art of photography is fast resolving itself into a mechanical science—is, in fact (to be paradoxical), settling into a state of unsettled complexity. I will not waste your time by enumerating all the reasons that impel me to make this assertion, but will be content with stating just one. It is relating to that portion of our art, namely, the correct exposure of gelatine plates. In these days of progression it is an undoubted fact that whenever a new idea is put forward that bears upon the face of it a faint possibility of overcoming certain difficulties which hitherto have had to be contended with, infatuated and indiscreet persons seize hold of the said idea, and look upon it as a satisfactory ending to all their past troubles, and a reliable forerunner of future successes. This forcibly applies to the present popular system of using actinometers and "Comparative Exposure Tables." I do not deny that this system is of use to the amateur, who, for the most part, depends upon scientific principles for the production of scientific results; but to the professional, to whom photography is (or should be) an art, the system is not only useless, but misleading. I have in my possession no less than six "comparative" tables compiled by various mathematicians; I have worked by each of these separately, and by computations made by their combined aid, but I may truly say that the negatives taken in each case were not (as I considered) so correctly exposed as those whose exposure depended on my experience alone. I do not endorse the opinion of some who assert that gelatine plates possess an enormous latitude, but I do opine that they do possess a certain amount of latitude, and when an individual has expended years to acquire an experience and a judgment so accurate as to enable him, under any condition of light, and without recourse to any mathematical rules, to bring his exposure within that latitude, is it not the height of absurdity for that individual to throw aside this extremely valuable acquirement and adopt in its stead a system which, if it does occasionally succeed, on the whole leads him into more blunders than would occur without its use?

There are some, perhaps, who will say, "Is it not by this system that we acquire this same experience?" To such persons I would quote the following fable:—"A dog, holding in its mouth a piece of flesh, was crossing a bridge, when he saw his shadow reflected in the water. Impelled by greed, he made a dart at the reflection, and by his eagerness lost the genuine piece of flesh which he had." Does not this apply to those individuals who, having acquired the experience I speak of by devoting their time to the study of these "mechanical aids," grasp at the shadow of a higher experience, and by their indiscreet energy, lose the genuine experience they formerly possessed?

But, gentlemen, I must crave your pardon for carrying this subject so far. Before I conclude, however, I will venture a word of advice to amateurs. If perforce you must adopt some mechanical system, ascertain by the little experience you possess the most serviceable and correct one, then stick to that, and that only, relying not so much upon the rules themselves as on the experience you may happen to gain by the use of them.—I am, yours, &c.,

W. INGOLES ROGERS.

St. Germans, August 16, 1887.

AN EXPLANATION.

To the Editors.

GENTLEMEN,—What I write about will unfortunately be a very old affair by the time this reaches you, but I ask you to let me have space for a word of explanation. It has reference to the report in your paper of the more than kindly way in which I was entertained by photographers in New York. I am reported to have said—or, rather, the report gives the impression that I stated—of English photographers, that they were more reticent in communicating their experiences to others than were American photographers. Now this is scarcely true, although I found American photographers quite as willing to impart information as English, and I did not say it; or, rather, let me say I had certainly no intention of saying anything of the kind. I gladly, however, take the blame of any ambiguity on myself. The comparison I drew had regard to non-technical matters—to hospitality, I mean. I do not believe that an American photographer, a total stranger, would be received in England with the overwhelming hospitality with which I was received in New York. The English—particularly Londoners—are, to strangers, probably the least hospitable people in the whole world, with the exception of the Chinese.

Another thing I said—also quite true—was that, contrary to expectation, I had found amongst American photographers much less of what I can only term "bounce" than amongst English. There are one or two English photographers I wot of, concerning whom it might be said that, were a stranger to be conveyed into the society of one of them, to spend a day in that society, and then to go back to his native land, having seen no other photographer, he would return with the conviction that to the individual he had seen was due the credit of every improvement that had ever been made in photography, if not, indeed, the invention of the science itself. Of course, it may only have been due to my brief stay in America that I found no such individuals there. At any rate, I did not find any.—I am, yours, &c.,

W. K. BURTON.

Answers to Correspondents.

PHOTOGRAPHS REGISTERED:—

J. H. Mann, Sandall, near Doncaster.—*Landscape photograph of Roche Abbey, near Doncaster.*
Hopkins Brothers, Huddesdon.—*Eight photographs of Huddesdon on Jubilee Day, June 21, 1887.*

WILLIAM A. BRICE (Geneva).—The matter is receiving careful consideration, and you will be communicated with privately.

J. E. GOWER.—The tentative system adopted by you, if carefully carried out, leaves nothing to be desired. Unless the salts are chemically pure it would be of no use to give definite proportions.

G. A. TURNER.—The process known as "lichtdruck" in Germany is simply what is known in this country as the collotype process. This process here passes under several different names, according to the fancy of those who work it.

A. VOSEY.—Platinotypes cannot be produced on highly albumenised paper so as to have the appearance of silver prints with the stability of platinum. Vigorous negatives are necessary to produce vigorous prints by the platinum process; weak and foggy negatives are unsuitable.

W. L.—We should not advise you to tamper with the carbon enlargement. It is more than doubtful if you will be able to reduce the print by treating it with very hot water. Certainly you will not if it has been alumed and the aluming action has been complete. Your best plan will be to get a lighter print made.

W. G. O.—Any of the photographic dealers at the places you stop at will supply you with dry plates. Perhaps, however, at some of the minor places they may not keep all brands, and you do not say which you will require. Would it not be better for you to take a full supply with you, so as to make sure of getting what you want?

G. Y. G. sends us some transparencies on glass in platinum. This is the second time this correspondent has sent us examples by the process. Those now sent are certainly an improvement on the previous ones. If our correspondent will send us the method by which they were produced we shall have pleasure in publishing it; he will then secure the credit of his invention.

H. B. writes: "I have a lot of plain photographs, and wish to mount them in a scrap album. Can you inform me, through your JOURNAL, how to make a mountant that will not cockle them?"—The best mountant for the purpose is a solution of gelatine containing a large proportion of alcohol. The gelatine best suited for making the solution is that recommended in a sub-leader last week.

LOLA.—For the over exposed plates already developed—rather than incur the risks of intensification—it will be better to make another negative through the agency of a transparency. But thin negatives of this class may be made on bromide paper taken with a brief exposure and a long development. As for the undeveloped plates, they can all be made to yield good vigorous negatives by a liberal employment of bromide in the developer and reducing the alkali to a minimum.

SIR DAVID SALOMONS sends us a capital photograph of the arc light, which shows very distinctly the form of the incandescent carbon. He also furnishes the particulars by which the picture was produced. He says: "Enclosed is a photograph of the 'arc' of an arc lamp burning with a current of twenty amperes (namely, about two thousand to five thousand candle power). Exposure was four seconds; intensity, one hundred and twenty-eight by Dallmeyer standard. The result was accomplished by transmitting the rays through a polariscope before reaching the lens. The lens was sixteen inches from the 'arc.'"

A. H. DEATH writes: "A few weeks ago I was requested by the owner of a painting to photograph the same. This was done and prints supplied, and on offering to give the negatives up I was told I could retain them and make what use I pleased of them; consequently other prints were taken off and exhibited for sale. Now the artist (who sold the painting to my customer) says I am not within my legal right in thus exposing the prints for sale, and demands their withdrawal; but before doing so I wish you to inform me whether I have done wrong or not in selling those copies."—In reply: An artist may sell a picture and still retain the copyright in his own hands, as a separate and independent property. It is possible that he has done so in this case. This you can ascertain from the owner of the painting.

J. G. BRADEN writes as follows: "Would you kindly tell me where I am at fault in the following matter?—My favourite toning bath used to be the acetate, latterly I have come to grief in this way: I make a bath of one grain gold chloride, thirty grains soda acetate, and water, eight ounces, keeping it at least eighteen hours before use; after toning one half-plate print and putting aside for further use I find my gold all gone down and the solution of a deep blue colour, refusing to tone again. I have tried distilled water and obtained the purest acetate, but with like disappointing results. I have also treated the prints after washing to a soda bath, but with the same effect."—Clearly something has been introduced into the bath, probably with the print, which has caused the reduction of the gold. If a toning bath be exposed to light that will in time bring about a precipitation of the gold. This may be the case in the present instance.

G. A. C. says: "Recently I had occasion to intensify a thin negative, using bichloride of mercury, iodide of potassium, and afterwards a weak bath of ammonia as usual; it was then put away to dry, which it did, with the exception of some streaks where the water seems to have collected in or under the film. Being in a hurry, the drying was hastened over a gentle heat, but when this was done the streaks where the water bubbles had formed were almost clear glass, even on parts which were comparatively dense, and they required retouching with brush and pencil before anything could be printed from the negative. Can you assign any reason for this? I think, myself, the hastened drying had much to do with it, but why?"—The reason is not far to seek. The film where there were streaks and bubbles evidently contained sufficient water to bring the gelatine into a state of solution, hence on applying heat the image there became disintegrated.

B. CLEWS.—So far as we know, the process, or anything analogous to it, has not been patented. However, there is no novelty in it. Thirty years or more ago it was worked, though only to a limited extent.

PUZZLED writes as follows: "If you could give me your opinion on the following case, I should feel much obliged:—A lady anxious to have a photograph of her grandchild has the little one photographed without the knowledge or consent of the child's father (the child alone as well as with herself). The father of the child coming to know of it (the mother is dead) prohibits the photographer from printing or supplying any of the photographs, but is willing to pay expenses. The lady does not see why she should not have photographs, though the child is on her knee; and the child's father is equally firm she must not have a photograph of the child. Meantime the photographer retains the negatives, and refuses to give prints from them to any party. I would ask—1. Can the grandmother claim to have the photographs? 2. Can the father legally prevent? 3. Can the photographer retain the negatives and refuse to supply prints from them to either party? Or, 4. What would be right to do in the circumstances?"—As the matter stands we know of no law that will meet the case. The father clearly has no copyright in his child's face. The one who commissioned the photographer appears to be the one entitled to the portraits. We leave this knotty question open to the opinions of readers, some of whom may have had similar experience.

UP till going to press we have not received from the engraver the key block of the Convention group we promised for this issue.

THE *Indispensable Bicyclist's Handy Book* is the title of a most compendious work on bicycling by Henry Sturmey (London: Iliffe & Son, Fleet-street). It forms a complete cyclopædia, and is profusely illustrated.

H.R.H. PRINCE ALBERT VICTOR gave Mr. Bassano sittings for photographs at his studio in Old Bond-street on Monday morning. Some very successful negatives are said to have been taken of His Royal Highness.

FROM MESSRS. BERNSTEIN & VOGT, 28, Jewry-street, E.C., we have received sample sheets of their improved Dresden double extra brilliant albumenised paper, which we find on trial to bear out all that they allege in its favour.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The usual monthly technical meeting of this Society will take place Tuesday next, August 23, at eight p.m., at the Gallery, 5A, Pall Mall East. Doors open at seven for reading and conversation.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, August 24, 1887, will be on *The Production of Transparencies*. Saturday outing at West Drayton. Train, Bishop's-road at eight minutes past two.

ROYAL CORNWALL POLYTECHNIC SOCIETY.—The Exhibition of this Society opens on September 6, therefore it behoves those who intend exhibiting photographs or appliances to be getting ready. Particulars will be found in our advertising columns.

A COPY, "With compliments of *Anthony's Photographic Bulletin*," has been received of a memorandum book which, we learn, was presented to each visitor at the Chicago Convention of the Photographers' Association of America by Messrs. E. & H. T. Anthony & Co., of New York. It forms a useful little pocket book.

ONE of the most charming pictures that we have seen for some time has been received from Mr. John M. Skinner, of the Albion Albumenising Company, Glasgow. It is an enlargement from a small negative taken by Mr. Skinner on the occasion of one of the excursions (that at Largs) of the Photographic Convention, and represents the champion yacht "Thistle" careening over a calm sea, the wind being but light.

MESSRS. M. & T. SCOTT, photo-enlargers and finishers, 36, George-street, Edinburgh, have sent us a specimen of a new style of photo-etching they have introduced. It is a platinotype enlargement from a cabinet portrait, and is of a very warm tone. While it is unmistakably a photograph, yet is it etched most skilfully and elaborately, so much so as to be entitled to take rank among works pertaining to the etcher's art. It is, indeed, a happy combination of the two arts. The subject is a weather-beaten old man, whose rugged features lend themselves well to this class of treatment.

HONOUR TO AN OPTICIAN.—SIR HOWARD GRUBB.—The honour of knighthood conferred on Mr. Howard Grubb was yesterday everywhere throughout the city spoken of with gratification. It was recognised as a compliment to science, and an acknowledgment of the recipient's high attainments therein. It may not be known to the general body of the citizens, though of course it is well known to all scientific men, that Mr. Grubb so far back as 1870 was elected a Fellow of the Royal Astronomical Society. In 1872 there was added to this distinction that of Honorary Membership of the Royal Institute of Civil Engineers in Ireland. In 1876 Mr. Grubb was presented with the Mastership of Engineering (*honoris causa*) by the University of Dublin. And this does not exhaust the list of the honours bestowed upon him by the magnates of science. In 1881 he was given the Cunningham Gold Medal of the Royal Irish Academy—a very high reward and proof of eminence; and, lastly, in 1883, he was elected a Fellow of the Royal Society. It will thus be seen that Mr. Grubb's knighthood represents no mark of accidental favour, but is such a recognition of his scientific abilities as will be accepted by the scientific world as a suitable and just endorsement of superiority and genius.—*Irish Times*.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1425. VOL. XXXIV.—AUGUST 26, 1887.

THE EFFECT OF QUANTITY OF SOLUTION ON DEVELOPMENT.

BEYOND an occasional passing thought on the subject of comparative economy, it is to be questioned whether one operator in fifty ever gives the slightest attention to the probable effect exercised upon the character of the negative by the quantity of developing solution used in its production. Perhaps even when the matter is thus put before them for the first time there will be some who will pool, pooh, the suggestion, and pass it off with a smile of incredulous superiority, as being quite too ridiculous to occupy a moment's thought. Such individuals notwithstanding, let us for a few minutes consider what effect the volume of developing solution may have upon the resulting image.

In this consideration we put entirely on one side the element of economy which we must naturally expect to prevail in most quarters, though not certainly to the same extent at the present time and with pyro at a shilling an ounce as ten years ago when gelatine plates were young and English pyro sold for three shillings and sixpence. Then the item of pyro formed a very serious charge upon the photographer's pocket, for not only was it far more expensive than the iron developer to which he had been accustomed with wet plates, but it had to be used in far greater proportionate quantity, ounces being required where drachms had formerly sufficed. We say advisedly "*had*" to be used in greater quantity," for if it had been found possible to develop without the aid of the dish many would have been the early gelatine converts who would gladly have availed themselves of the facility. It was not to be so, however, and they were compelled to forego the pleasure of limiting the quantity of solution; but as the mountain would not go to Mahomet, that individual in the natural course of events proceeded to the mountain. The extra demand for pyro was rapidly met, and as rapidly the price came down, until at the present time the cost of the pyro developer has ceased to be the serious matter it formerly was.

The prime reason for not discarding the developing dish, or rather for having recourse to it in the first instance, was the impossibility of keeping a small quantity of solution evenly spread over the surface of the gelatine plate—a matter of the greatest ease with collodion. The refusal of the developer to flow led to great irregularity in the formation of the image, to streaks, stains, and smears innumerable, so the dish had to come into general use. Even then those economically inclined did their best to get along with the smallest possible quantity of solution, a quantity insufficient to cover the whole film at once, but which, by dint of vigorous rocking and agitation, was made to traverse every portion of the plate at pretty

regular intervals and with tolerable uniformity. But then other troubles arose; the developer became literally so "lashed into foam" that the resulting markings from air-bubbles constituted a fresh subject for serious consideration. Then, again, it was realised that the fierce agitation to which the solution was subjected, by bringing it so much more into contact with the atmosphere, caused its speedy oxidation and discolouration, and this, taken in connexion with the exposure of the film itself to oxidising influences in the intervals when it was not covered with solution, led to the staining of the gelatine a most uncompromising and inconvenient brown. As this was prior to the days of the sulphite developer and clearing solutions, it proved effectual in calming the last struggles for economy of pyro.

These possible results directly attributable to the volume of solution having been enumerated, it may be said that we have exhausted our subject, but we think not yet. Let us turn back to former days and see if we find any analogy in wet-plate development. The circumstances and conditions were, we grant, quite different, but they will serve our purpose and lead us to show where even with alkaline pyro or ferrous oxalate an important and perhaps still greater influence is exercised by the mere quantity of solution applied to the plate.

If we inquired of some of our old wet-plate readers what would have been their course of procedure in developing a subject in which it was necessary as far as possible to subdue the contrasts where, in fact, it was the object to gain a soft result by artificial means, the reply would, we fancy, be unanimous: a large quantity of developer would be used, flooded quickly over the plate, and a portion of it allowed to escape over the edges of the glass. Conversely, where the object was to get as much contrast and density as possible, the quantity of solution would be kept at the minimum and the plate rocked as carefully as a sleeping babe, to avoid losing a single drop of the precious fluid. What is the *rationale* of these modes of treatment? Simply this, that the silver solution adhering to the plate after its removal from the bath is the agent that gives force to the development, and, consequently, by diluting it with a large quantity of iron solution and allowing some of it to escape, the character of the image becomes less vigorous, while, on the other hand, by concentrating it as far as possible, by using a minimum of iron and retaining every drop of silver on the film, the greatest amount of density is attained that the plate is capable of giving.

Another practice amongst expert workers when aiming at similar results was to rock the plate constantly where contrast was sought, or to allow it to remain stationary when softness was desired. The explanation of this procedure was that when

the solution is allowed to remain quiescent upon the film those portions of the latter which have been more fully impressed by light rapidly attract to themselves the silver in the layer of solution in their immediate vicinity and quickly exhaust it, arriving at their maximum effect before the half tones and shadows have, in their more leisurely manner, taken to themselves the quantity of silver they require. The lights are in fact held back, from the mere absence of silver to increase the depth of the deposit, while the half tones are slowly gaining strength, and when the latter have reached the proper point the developer with its unreduced silver is poured away. But if, instead of allowing the plate to remain still, it be constantly rocked, the solution is kept thoroughly mixed, and as rapidly as the high lights extract the silver from the solution for the time in contact with them it is replaced by more from the surrounding portions, and they go on acquiring density by a species of robbery of the half tones and shadows, and so contrast is increased.

It can be readily seen from what we have said that the quantity of developer has, here, a very important bearing upon the character of the image; it has, in fact, precisely the same effect as the addition or omission of a certain quantity of one of the most important agents in the reaction. For clearly the application to a wet plate of half an ounce, instead of two drachms, of developer would have an effect in every way tantamount to adding one grain of silver to the ounce instead of two if the silver had to be added in that manner, instead of being already on the film; or it would be similar in its result to using a one grain solution of pyro in place of a two grain in modern development. It may be surmised, as a corollary to the above, that if an infinite quantity of solution could be applied to a plate and instantly mixed with its silver, the result, so far as development is concerned, would be practically *nil*, as it would be equivalent to washing out all but the most infinitesimal trace of the silver required to build up the image.

After this we are quite prepared for a chorus of corrections, and fully expect to be reminded that there is no free silver to be dealt with in the case of a dry plate; that as the developer is made up to a definite formula and does its work without any extraneous assistance beyond the previous action of light it matters not whether a drachm or a gallon be employed. To put it plainly, we expect to be reminded that the alkaline developer or ferrous oxalate is practically a one-solution developer, while the iron developer is virtually a two solution, since it derives its silver from the silver bath, and that the dry plate developer consequently works independently of the plate. Does it? We shall see.

Before going into any explanations on the subject, let us first try the simple experiment. Let us expose a plate and cut it in halves. We will mix ten ounces of developer, let it be alkaline pyro or ferrous oxalate, it matters not so long as it is mixed complete and is perfectly uniform throughout the bulk. Now we will divide it into two unequal portions—two ounces and eight ounces—and immerse in each one half of the exposed plate. With the exception of the difference of quantity let the two plates be heated in precisely the same manner, rocked simultaneously, and the solution poured off each at the same time. Surely if there were any truth in the allegation that the volume of developer mattered nothing we should have two identical images so far, at least, as character goes; but what do we see? Well, simply that the half plate treated with the smaller quantity of solution exhibits more contrast than the other; we do not say that it is denser—it may be it is less

dense—but there is more clearness in the shadows and less vigour in the finer details. There may be quite as much shadow detail visible in the one as in the other, but in the half treated with the greater bulk of solution it has more printing value. Repeat the experiment with varying quantities, the result is always the same, and though the difference may not sometimes be great still a difference there is.

Let us try another experiment. Expose and cut a plate as before and immerse the halves in separate *equal* quantities of the same developer, but during development allow one dish to remain perfectly still while the other is constantly rocked. Arguing on the analogy of the wet plate under similar conditions, the rocked plate should be strong and vigorous and full of contrast while the other should be softer and more harmonious. We do not find these characters, however, quite borne out, for though the rocked plate may be vigorous and satisfactory as a negative should be, the other presents a miserable image that is neither vigorous nor soft, but apparently a hopeless case of under exposure.

The last experiment will help us to point where the discrepancy lies. In the case of the wet plate the greater softness resulting from permitting the plate to lie still during development is attributed to the more rapid exhaustion of the silver in contact with the high lights; the same argument may be applied in this case, and we can suppose that exhaustion of the solution would have the same effect. But it has not. We imagined a short time ago somebody informing us that the dry plate developer works independently of the plate; it does not, for though, as we have already said, the circumstances and conditions of wet and dry plate development are quite different, still in each case the developer as applied to the plate derives *something* from the film itself—silver in the case of the wet plate, bromine in that of the dry. In one instance an aid to the formation of the image, in the other a check or retarder.

Now, in the case of our last experiment, the explanation is plain enough, and the necessity for at least gently rocking the plate during development is shown. Not only does it renew the exhausted developer by bringing fresh solution into contact with the film, but it removes and dilutes the evolved bromine, which would otherwise react directly upon the undeveloped image. Such is, indeed, the explanation of the behaviour of the unrocked plate; no sooner is a visible image produced but the energy of the developer is weakened or altogether destroyed. At the same time a quantity of bromine is evolved from the reduced silver bromide, and this, in the absence of any alkali to combine with, remains in contact with the film in the form of hydrobromic acid—not only a restrainer, but a destroyer of the action of light. This, then, suffices fully to explain the result, and especially the difference in the behaviour of wet and dry plates respectively.

Turning to the first experiment, which more immediately bears upon our subject, we have, of course, again to deal with the liberated bromine, but in this instance the effect resolves itself simply of more or less additional restraining power. In the experiment quoted, supposing that we started with an entirely unrestrained developer, the smaller quantity would, at the finish, and at every stage of development, be precisely four times as heavily restrained as the other, since the same quantity of liberated bromine (converted into bromide) would be concentrated in one-fourth of the quantity of active solution.

We have overstepped the space at our command already, or should proceed to show where this question of quantity chiefly bears upon actual practice, but this we must defer. We have

said that the difference, even in an extreme case like our experiment, may not be great, but, as we hope to prove, there are circumstances under which the variation of the quantity of the developing solution may play an important part.

THE COLOUR OF SILVER PRINTS.

AN interesting example of the change of taste that all things artistic are liable to be influenced by may be seen in the characteristic "tones" or colours of the silver prints of the present day. About a quarter of a century ago, when negatives of extreme density were the rule, the prevailing colour of almost all albumenised prints, toned by the alkaline bath, was a purplish black; or, perhaps, we should say, that colour was the one usually aimed at by the printer of the period. Within the last ten years a complete change in the colour of prints sent out by the average photographer has taken place; the production of purple tones is now far "more honoured in the breach than in the observance." The question whether caprice and the desire for change, or some action of a more occult character, may be suggested as the motive cause, comes readily forward. Our own opinion inclines to the explanation being found in a combination of reasons.

The desire to bring something new before his clients may well be supposed to actuate the professional photographer, and, no doubt, it does, thus explaining one of these causes. We are most inclined, however, to the opinion that the chief one lies in the difficulty of uniformly attaining the purple tone in the bulk of the prints turned out by any one establishment. A glance at our correspondence columns suffices to show how frequently the photographer fails to realise the fact, that unless the negative be good the prints from it will not be good, or, to speak still more pointedly, that the tone of a print is governed to a great extent by the *timbre* of the negative from which it is obtained.

Since the introduction of gelatine plates the class of negative produced has undergone a radical change, delicacy rather than force now characterising them, while a tendency to the once hated fog has been so very common that a little fog more or less has come to be looked upon as almost a necessary evil—"fog," that is, as it would be called by an old hand at wet plate work. Now as the very essence of the once admired effect of the purplish black is force and brilliancy as opposed to an excess of softness and delicacy, it is quite natural that with plates of the latter character other "tones" should be chosen, and such, as our readers are aware, has been the case.

But beyond this, the albumenised paper manufacturers, seeing the growing taste for warmer tones, have gradually arrived at a process of manufacture which enables them to turn out a class of paper upon which it may be said that, practically speaking, it is next to impossible to obtain purple tones. We once heard an experienced photographer say, "Any one can get brown tones; it takes a good workman to get a rich purple on his prints." We have thus, through the influence of the paper maker, a very cogent reason for the abandonment of the cooler range of colours. We do not say total abandonment, for there is still a band of workers, most, if not all, of them old photographers, who even yet are staunch adherents of this old favourite.

Granted, however, the production of negatives from which nothing but cold and leaden-hued prints could be obtained, the establishment of another range of colours rich in their own way would naturally be an object with good workmen, and we have seen such colours hold the field for years past. Our

own opinion is that—using a negative that is suitable—the purple-toned prints afford greater range of effects and greater brilliancy, richness, and force than any other colour since chosen.

Still more lately there have been produced pictures of a very fascinating character, in which the colour is about the furthest remove from purple that a silver print is capable of exhibiting. The pictures in this "tone" that we are thinking of already before the public are of considerable artistic merit, hence we may safely predict that there will be a run upon it for a time, as the attractiveness of the portraits will be set down, in a general way, by the unthinking, as being due to the colour of the prints and not to the artistic skill of their producer.

In regard to the mode of obtaining such tones—as to which we have already been asked for instructions—it may be said that most of the old baths when in good working order will be capable of producing them. The toning bath, perhaps, least adapted is the chloride of lime bath. This particular toning solution is, we are inclined to believe, the most difficult of any to attain proficiency of working with; but, given a good negative, a solution in proper order, suitable paper, and an experienced hand to work it, prints of a quality more approaching to that of an engraving than is attainable with any other formula can, we are of opinion, be produced.

There is, of course, always to be found a class of negatives which, whatever colour the photographer may in an ordinary way require, will always be most effective when printed in warm tones, and when a bath chosen for its suitability for purple tones is employed a considerable degree of under toning will be desirable for these warm colours.

If warm shades alone be affected we cannot advise our readers better than to stick to the old acetate bath made of about twenty grains of acetate of soda added to a grain of recently neutralised chloride of gold with plenty of water. The latter is a most important matter: it is most difficult to get uniform warm tones with a bath that tones the pictures in a minute or two; more than that, the most delicate and even colours cannot be obtained rapidly.

One of the most remarkable additions possible to the range of colours was shown to be within our power when the "burnisher" was first introduced, and, indeed, we are not at all sure that the introduction of this instrument did not aid more than any other cause in sounding the death knell of blue-toned prints.

The advantage to colour producible by the aid of heat had long been known, but it was reserved to the introducers of the "burnisher" to show the most remarkable difference which heat could produce in an average print. It gave so great a richness and transparency to the shadows, combined with a general enriching of the whole effect, even with an indifferent print, that at one time almost every one burnished his prints. The extreme gloss given to the surface was by many supposed to be the cause of the improvement, and for many years the majority of *cartes-de-visite* produced in this country were burnished. When cabinets became more general, burnishing fell out of use to a great extent; now we are promised another reign of the hot iron.

This latest colour—that promises to become fashionable—is still more inclined to yellow than to ruddy brown, and to obtain it the photographer must either not tone at all or else give his prints a mere dip into the bath. But, above all, he will have to burnish. An acid floating bath is here of little harm,

if, indeed, it be not a positive advantage, and the negative may be very thin and still allow beautiful prints to be obtained from it.

The artistic mind tends to revolt against the garish effect of a highly "burnished" print, but, seeing that the gloss and the amelioration of the colour are inseparable, we are afraid that protest will be useless. Let, however, every one try to put his whole mind into his work, and he will reap the reward in an appreciative *clientèle*, and let him remember that the colour of a print is but one—a minor—condition of artistic expression.

FROM accounts which have reached us up to the time of writing, photography with the eclipse expeditions has not been so successful as could have been desired—at least as far as Europe is concerned—owing to the condition of the atmosphere at the time. In Prussia and in Austria we learn the results have been unsatisfactory. Russia, on the whole, seems to have been better favoured, as a report from there says that two or three good negatives of the corona have been secured. It is indeed a disappointment when great preparations have been made, heavy expenses incurred, and hundreds, perhaps thousands, of miles travelled, to have the whole object frustrated by a few heavy clouds. Such circumstances, unfortunately, are by no means unknown to scientific men in connection with eclipse expeditions.

SINCE the Abbé Larrieu issued his pamphlet in Paris alleging that the Great Wall of China has not, or ever has had, any existence except in the imagination of writers and travellers, considerable discussion on the subject has taken place here as well as on the Continent. Several letters have appeared in the daily papers from persons who have actually seen the wall in different places along its length. One correspondent says that he is in possession of a photograph of the wall which he purchased in China about a quarter of a century ago, taken by that well-known artist Signor Beato. A number of photographs of the wall, if they were forthcoming—and they should be—would prove more conclusively the fallacy of the Abbé's pamphlet than any amount of correspondence, however well it may be authenticated. In discussions of this kind photography is a better witness in the opinion of most people—and carries greater conviction with it—than the mere testimony of eye-witnesses.

THE production of a reversed negative, suitable for some of the photo-mechanical processes, sometimes proves troublesome to the ordinary portrait photographer. If he happen to be provided with a prism or a reversing mirror the thing is simple enough, but this is seldom the case; or if he have the materials to hand for working the wet collodion process, which few have nowadays, it is easy to take the negative on a waxed plate, or one treated with French chalk, and then to transfer the film to a sheet of gelatine. The most general plan now adopted is to take the negative on a dry plate in the ordinary way and then to reproduce it reversed in the copying camera. Now, however skilfully this work may be carried out, it is seldom that the reproduction comes up to the original in quality. In Germany, and other parts of the Continent where mechanical processes—collotype in particular—are more general than here, and also in America, dry plates, prepared so that the film can be easily removed, are regular articles of commerce. Here, we suspect, the demand for stripping plates would be so limited that it would scarcely pay English makers to put such plates into the market. However, the thing might be worthy of consideration.

ONE of the simplest, and at the same time best, plans open to those who are not in possession of either of the above means of obtaining reversed negatives, is to take advantage of the Eastman stripping films. With these, when used for our present purpose, the negative is taken in the ordinary way, developed, fixed, and washed. Then a glass plate is coated with plain collodion, plunged into water, and as soon as the ether and alcohol are removed, the wet negative is squeezed down upon it. After resting for a short time the plate is placed in warm water, when the paper comes away, leaving the image attached to the glass plate. We have here a reversed direct negative on glass

as good in every way as if it were taken on a dry plate, and in printing from it there is no intervening film to interfere with the sharpness of the image. There is yet a further advantage in this method of procedure, as the negative may be made to serve a double purpose. If the glass be rubbed over with French chalk, previous to coating it with the collodion, then, when the negative has served its purpose as a reversed one, a pellicle of gelatine can be applied, after which the negative can be stripped off from the glass and utilised for silver or platinum printing.

AN excellent opportunity was afforded during the severe storm last week for obtaining photographs of lightning. Seldom, indeed, has such a chance occurred, the night being dark, and the lightning unusually brilliant. Those who watched the storm could not but be struck with the great dissimilarity in the appearance of the flashes with most of the photographs which have from time to time been exhibited. Indeed, no two discharges appeared to the observer to bear any relation whatever to each other, either in form or the direction they took. A photograph of lightning at the instant of its "striking" an object, as in the case of the church in the neighbourhood of Long Acre, would be exceedingly interesting and extremely valuable from a scientific point of view. Such a photograph would, doubtless, show the lightning very differently from what it is depicted by artists in a painting of a thunderstorm.

AS might be expected, we have received several photographs both of the lightning itself and its effects produced during the recent storm. One of the former is by Mr. Joseph Gray, who has secured a most eccentric flash, more so than we have ever seen; another by Mr. Brebaza shows the interior of a studio as displayed by an exposure of twenty minutes during the storm.

OF late years photography has been largely applied in the production of Christmas and New Year's cards. Those who intend to make a speciality of it this year should lose no time in getting up their specimens. Of course, we are not alluding here to those photographic cards which are supplied by the wholesale houses to the retail stationers, as with these the latter have already laid in their winter stock. The kind we allude to are those supplied by many photographers in the provinces of local scenery taken by themselves, and mounted on neat cards bearing seasonable greetings. Already we have seen some capital examples of these in the window of a photographer in a country town. A photograph of a well selected view taken in the neighbourhood of the sender's abode, or, perhaps, better still, the portrait of the sender, accompanied by seasonable wishes, would generally be more acceptable than the majority of cards now in vogue. Extensively as photography is now being utilised for Christmas, New Year's, and birthday cards, it might be still further employed if photographers themselves made it more a speciality, instead of leaving the whole of the business in that direction in the hands of the wholesale stationers, who supply only well hackneyed subjects, and often of little interest.

IMPROVING FEEBLE NEGATIVES.

IT not unfrequently happens that in consequence of error in exposure or injudicious development we find after fixing a negative that it is too thin to give a satisfactory print, though the gradations of light and shade are tolerably correct. In such cases, if the shadows are perfectly clear, it may be an easy matter to give the additional force by means of one or other of the numerous methods of intensification in general vogue; but too often that is the one condition that does not prevail, and to intensify by chemical means is the opposite of beneficial. Perchance the subject may be one of some little value, and the slightest suspicion of uncertainty as to the probable result suffices to deter us from any attempt in that direction. Under such circumstances, I have often found it useful to resort to the beautiful but little practised "dusting on" process.

This offers many advantages for the purpose, not the least being that it leaves the original image quite intact, so that if the first operation prove unsatisfactory we are at least no worse off than before,

and by cleaning off the first failure we may start afresh with the added knowledge of the particular requirements of the case gained in the unsuccessful experiment. The process, too, is a direct one, the auxiliary negative image being formed in a single operation without the intermediary of a positive or any reversing operation. In addition, great scope is afforded for local treatment, any portions of the image that may be already sufficiently dense being easily left out of the general treatment, and so the method becomes specially valuable for that class of subjects which are most difficult to deal with in the ordinary manner, where wide contrasts of lighting are presented to the camera.

Most of my readers are, I dare say, familiar with the general principles of the process, though, perhaps, not acquainted with its practical working, and to such it will be sufficient to give a few hints that may be useful in applying the method to this particular use. For the benefit of those who are entirely ignorant on the subject I may briefly recapitulate the details of procedure.

In the first place, a sheet of perfectly clean glass—in this case the back of the negative—is coated with a mixture of gum, gelatine, albumen, or similar substance, with a certain proportion of hygroscopic matter and a bichromate. This coating is thoroughly dried in the dark by heat, and then forms a hard, varnish like surface, which, however, rapidly absorbs moisture from the atmosphere, and becomes "tacky" as the plate cools, in which condition any fine powder dusted over the surface becomes adherent. It possesses the property, upon exposure to light, of losing its attraction for moisture, hence, when exposed under a negative to sun or diffused light, the clear shadows of the negative permitting the light to pass through, the corresponding portions of the sensitive film are hardened, and lose their power of attaching the powder subsequently dusted on, the parts protected by the negative image at the same time retaining the tendency to absorption. In this manner an image is formed by the fine powdery matter adhering to the protected parts of the plate—the parts which are unacted on by light—and so a negative image is formed *from a negative*. Such briefly is the principle of the process, the details of which I will attempt to explain.

Several formulae for the sensitive solution will be found at the latter end of the ALMANAC, but for this particular purpose I prefer a slight modification of that marked No. 1, as it gives a clearer film and one which is more under control in development than some of the others. To save the trouble of reference I repeat the formula here, as I have modified it; the solution is practically the same in the end, but I prefer to use a definite quantity of bichromate rather than so much "saturated solution." Take—

Bichromate of ammonium	150 grains.
Honey.....	180 "
Albumen.....	180 "
Water	4½ fluid ounces.

Dissolve the bichromate and the honey in the water, warm, and allow the solution to cool; then stir in the albumen until thoroughly mixed, but do not beat it, and when quite dissolved filter very carefully, repeating the operation two or three times if needful. Great importance attaches to the filtration, as upon the care with which that is done depends the beauty of the final result, the slightest speck of dust or floating matter giving rise to ugly blemishes on the film. This solution will keep good for some days in the dark. In very dry weather the proportion of honey may be increased and *vice versa*, of which more anon.

And now to apply it to the plate. Naturally, as we are dealing with a plate of glass already carrying a negative film, the operation is one that requires more care than if the reverse side of the glass were free. The back of the negative, it must be understood, is to be coated, and the first point requiring care is that none of the solution shall get on to the front. This, however, is easily managed in careful hands. At one time I preferred to varnish the negative before coating the back, but I have come to the conclusion that it is, all things considered, safer to leave it unvarnished. Cleaning the back of the plate has to be seen to however before coating, and this must be done very thoroughly; all mechanical impurities, splashes, and smears of emulsion must be first very carefully removed, though this should be done before the negative is dried. Then the glass should be rubbed over with a mixture of alcohol and ammonia in equal parts, and finally polished with a clean silk handkerchief.

Next, we come to the arrangements for heating the negative, which is absolutely necessary in coating and drying. Clearly it would be unsafe to heat the plate over a naked flame, which would be nearly certain to smoke or otherwise injure the gelatine film, so we must provide a "hot plate." This is easily arranged by placing the lid of a large biscuit or other tin box at some distance above a spirit lamp or gas stove so as to equalise the temperature as much as possible. Then, by means of wedges, or in any more convenient manner, it must be arranged that the negative may be suspended in a perfectly level position at a slight distance, say, a quarter of an inch above the hot plate, so as to catch as much heat as possible without actually touching the metal. This done, we are ready for coating.

The plate must first be very carefully dusted. It is best, after polishing, to set the glass aside for some time until all electrical disturbance has subsided, and then to remove any adherent particles with a single stroke of a folded silk or cotton handkerchief, then, immediately before coating, to sweep the surface once more with a broad camel-hair brush. Next, taking the plate by one corner with the thumb and finger, pour on to the centre a pool of the sensitive mixture. It is nearly hopeless to expect it to flow "like collodion"—any attempt at that will almost certainly end fatally for the negative, for some of the solution is sure to find its way on to the front. The best way is, after deliberately setting down the bottle, to lead the solution up to the edges with the finger—which must be quite clean—and when that is done to pour off the surplus by one corner into another bottle, leaving only a very thin layer upon the glass.

Now, perhaps, the troubles will begin, especially if the glass be not really clean. The bichromated mixture will very likely show a tendency to run away from the glass in patches, especially near the edges. If this be the case a little coaxing with the finger, gently *rubbing* the solution into the bare patches, will often cure the evil; if not, there is nothing for it but to clean the plate and start afresh. When the sensitive solution is in proper condition the only cause of this can be imperfectly cleaned glass. Should it, however, prove obstinate and refractory, other measures will have to be taken, and nothing answers better in my hands than a substratum or preliminary moistening with a feebly alkaline saccharine solution. Sixty grains of loaf sugar and ten drops of ammonia dissolved in an ounce of water and well filtered, is rubbed evenly over the plate with a piece of old linen immediately before coating; the solution will then usually flow evenly without the assistance of the finger.

The glass, being evenly coated, is laid down upon the hot plate in as nearly a level position as may be, and there left until quite dry, in which state it will present an even, smooth, and glossy appearance. Too great heat must not be applied, or decomposition will be set up and the film ruined. A temperature of 150° Fahr. is as high as it is safe to go. When dry the plate is ready for exposure and must be exposed at once.

I may as well remark that these plates cannot be prepared and stored, but must be made just when required for use, since the moment they cool down to the natural temperature they commence to become tacky. On this account every precaution must be taken to avoid damp during the period of exposure. In the case of printing from another negative, both negative and plate must be placed in the printing frame *warm*; but in our case the negative—picture side downwards—is placed in a printing frame, and backed with a piece of black velvet or smooth cloth previously thoroughly dried and still hot, and the back of the frame immediately closed. The backing of cloth not only serves to lengthen the time the film may remain without becoming tacky, but it also prevents extraneous light getting to the film.

The time of exposure will vary very greatly according to circumstances of light as well as density of negative. With a thin negative, such as we are likely to have to deal with, an exposure of twenty or thirty seconds will suffice in full sunlight; but I much prefer to use diffused light, which gives far greater control. From three to five minutes ought to suffice at this time of year, and even in the depth of winter and in very damp weather the exposure will not be long enough to render the film adhesive if properly dried and backed at first as I have described. The question of correct exposure is of some importance, since, if it be too long, the powder refuses to adhere except in the very slightest degree, and no density can be obtained. On the other hand, if the time be too short, and especially in wet weather,

or when the atmosphere is heavily charged with moisture, the film absorbs the damp so greedily that the powder, unless great care and judgment are used, is laid on in heavy "dabs" wherever the brush touches. On the whole, however, I prefer to err on the side of under doing the exposure than the reverse, especially where local treatment is necessary, as by constantly rewarming the plate its tackiness can be very well held in check.

As regards the colour to be used, I do not think I have yet tried anything that is superior to the finely-powdered plumbago formerly used for making reproduced negatives. Its soapy nature renders it particularly suitable, and its fineness removes a tendency exhibited by many other powders to "pile up" in thick, coarse layers in the heavier shadows. I have tried, amongst other pigments, finely-powdered lampblack, but, irrespective of its greater cost, except for *over* exposed films it is inferior to plumbago. That I employ is the powdered plumbago of the oilshops sifted through muslin. A better preparation, and one requiring no sifting, is that used by electrotypers, and it is not expensive.

I find I shall have to leave the development for another paper.

II. Y. E. COTESWORTH.

ON THINGS IN GENERAL.

A CORRESPONDENT writing over the signature "A Painter" has the audacity first to hint, and afterwards boldly to assert, that "a portrait painter cannot receive any assistance by aid of photography." The thing is too ludicrous to use strong language over, but the statement appears to me about as conspicuously inexact as any ever launched upon the sea of controversy. It is, perhaps, sufficient that the Editors have said in a footnote to the letter that they know innumerable instances to the contrary. Take alone the number of posthumous paintings whose only claim to resemble the original is the likeness to a photograph taken before the subject died. Such portraits have been painted by the foremost painters of the day. But, lest "A Painter" should say that this is an evasion, I think I might point to the experience of almost every leading photographer of the day, who must have had portraits utilised for this purpose, if he have not, indeed, photographed sitters expressly for the use of the painters. I have a most distinct recollection of taking a gentleman's picture solely as an aid to the artist, who was painting a most costly presentation portrait of a public character, and I have myself supplied copies of portraits of my own taking to other artists for use in painting portraits. One gets used to the formula, "Just for a memorandum, you know:" but when the memorandum appears very plainly limned out upon the canvas one holds one's own opinion on the point.

There is, however, another, and I may say, distinctly, fraudulent, aspect that this subject sometimes presents, and which I cannot better describe than by narrating an instance that came within my own personal knowledge.

A well-known local magistrate in a town where I was once staying—it is now many years ago—invited me to see his art treasures, among them being two three-quarter length oil-paintings of himself and his wife. He had only given eighty guineas each for them, so that too much was not to be expected: they were, nevertheless, painted by an artist of repute. I quickly formed a very strong opinion about them, and was turning away from their neighbourhood when I was closely pressed for a criticism upon their merits. "My opinion, then, is that the heads are painted upon photographs pasted, or otherwise secured, upon the canvas." The worthy magistrate was indignant, and would not credit this for a moment. Years afterwards I was again in the same house, and I made a casual inquiry about the paintings. "Oh, the faces went all black, and the paintings are put into the lumber room." My original opinion was clearly a correct one, and the artist who perpetrated such a fraud was quite as worthy of punishment as Belt, the sculptor, who got eighteen months for misrepresentation when it was a matter of jewellery.

Talking of paint brings me to the suggestion for a backing material by a correspondent signing himself "R. Sedgfield," who recommends for a plate backing the contents of a tube of Newman's moist colour, purchasable, I suppose, at a shilling a tube. I am sure it would be a most useful material for the purpose, particularly so when the photographer had first gone out to make a sketch of his subject in

order to know where to smear the paint. I was always under the impression that the moist water colours were made with gum, water, glycerine, and pigment, so that the chief advantage of Mr. Sedgfield's method would be the giving of a shilling an ounce, say, for what could be easily made at fourpence a pound. As to smearing the fingers, why every one knows that the finer the state of comminution of the pigment particles, as would naturally be the case in prepared water colours, the more readily they will mess the fingers and the greater the difficulty of removing the smear. But perhaps it is a joke.

It needs a sufficiency of courage for even an experienced man who is *au fait* with his subject to start running a-tilt at a variety of objects which, though generally accepted as genuine, he considers to be impositions. He risks a fall at the outset; but when one most imperfectly equipped in the matter of knowledge of his subject starts on such a course, he is bound to fall ignominiously. Such has been the fate of a gentleman of Philadelphia, whose long article read at the Philadelphia Society, on *Some Photographic Heresies*, was recently given in the pages of this JOURNAL. Most of the attacks he makes serve but to show his want of acquaintance with his subject. With his countryman Mr. Carey Lea's recent investigations close under his nose, as one may say, he can actually speak of the best photographic writers being proverbially but indifferent photographers. Wet collodion, according to this gentleman, is to bury itself. What will the enlargers alone say to his proposition? When he gets on to the subject of dry plates he gets hopelessly adrift. He supposes photographers generally to be afraid of rapid plates, and that sparkle and latitude have to be sacrificed to rapidity; and finally says, "I hold that a good rapid plate is capable of doing all that a slow plate is, and much more besides." This is all sheer nonsense. A good photographer uses rapid plates whenever he wants great rapidity, and he knows it to be a fact that, at any rate with the majority of good plates purchasable, there is a vast difference in the working of quick and slow, and that these quick plates will not do all that slow plates will by a very long way. "Development is not the simple matter some people would have us believe." Who that knows how to develop considers it a "simple matter?" Mr. Truseott, not content with showing the capabilities of a south light in a studio, prefers it to a north. Again, he appears to think that Professor Burton is the first to discover the inaccuracy of the expression, "depth of focus;" and, of all absurd things in the world that he could do, Mr. T. falls foul of Mr. J. Traill Taylor in a question of photographic optics! I never met with such a tissue of erroneous notions and incongruities as this paper presents.

The new Antwerp Section of the Belgian Photographic Association rendered its initial meeting celebrated by the description of a method of preventing prints from cockling while drying. The plan soberly recommended was to steep them in a mixture of glycerine and water (nearly one half glycerine), and allow to dry. I wonder if the writer ever tried treacle, and I should expect, the next time he contributes, to hear of his having recommended birdlime as a mountant.

On the same page of our JOURNAL that I read this remarkable recommendation I observed that a sum of thirty-five thousand florins had been voted by the Municipal Council of Vienna as a subsidy towards a Photographic Institute. It would be a long time before such a subsidy were given in this country. There are always two sides to a question, and this suggests a sort of endowment of research the very mention of which sends off some people into a state bordering on frenzy. There are few who would doubt, however, that such a sum set apart in this country for a similar purpose would be capable of most valuable service. We have not to look far back to see what has become of those who have borne the heat and burden of the day in photographic discovery while their followers have reaped an easy harvest. I would not suggest an eleemosynary disposition of any such sum, but merely a slight smoothing of the thorny path of discovery by those earnest workers whose means do not enable them to follow the bent of their inventive skill.

FREE LANCE.

ECHOES FROM THE SOCIETIES.

I HAVE long been a staunch advocate of "slow development" for all ordinary purposes, that is except where the particular circumstances distinctly counter-indicate its advisability. By "slow development"

I mean careful, and what has been termed "tentative," treatment, as distinguished from piling on the full force of the developer at the outset and finishing the operation in a minute or two. I am fully conscious of the value of time, and should decidedly lay myself out to save it as far as possible, if I thought I could produce as uniformly good results time after time in two minutes as in five; but I am afraid that until correct exposure becomes a purely mechanical matter that is impossible. No harm is done to a slightly under exposed plate if the tentative system be followed, since the lack of exposure can be recognised at a very early stage of the proceedings, and the treatment modified accordingly. Similarly with over exposure. In fact, I may say that I, as a rule, follow the practice of Mr. H. J. Newton, though I do not call it, as he does, "always over exposing." It would be over exposure if I always followed it with high pressure development.

But when the high pressure system is adopted the giving of a "full exposure" becomes a risky, if not an impossible, practice, for one of two things must happen—either an unnecessary strain is thrown upon the operator during development or his results must suffer. The high pressure system of development is, to my mind, "taking hold of the wrong end of the stick." There is latitude both in exposure and development, but far more in the latter. Why, then, compel greater care and exactitude in exposure by working the elastic operation of development in a rigid and inflexible manner?

But with all my love for slow development, I think Mr. A. W. Beer sails beyond the bounds in his paper read before the Liverpool Amateur Photographic Association, in which he recommends the "American Standard" developer (has this anything to do with the "Stars and Stripes," it seems to have nearly as many ingredients) at *one-eighth* its normal strength. The probable result is well foreshadowed in his statement that "if no development appears in five minutes" he proceeds to strengthen it, and after waiting another similar period, if matters do not improve sufficiently he repeats the operation. I think things might easily proceed "quietly and sedately" without occupying that time; but if Mr. Beer is of a different opinion, I am afraid I for one could not agree to follow his advice—"Don't hurry."

Mr. Beer expressed himself to the effect, also, that pyro in solution is "uncertain," and that "dry pyro goes further in development than pyro in solution." This is distinctly contrary to my own experience. I have used pyro that has been in solution for upwards of twelve months that has, when tried against freshly dissolved, proved every whit as vigorous in its action. I have used dry pyro in the haphazard manner that used to prevail of shaking or ladling out of the bottle what was *estimated* to be the required quantity, and have been surprised to find what a hole a dozen plates make in an ounce under that system. I do not find that dry pyro goes further.

Speaking of estimating the quantity of pyro, I heard a good story some years ago of a then shining light in dry-plate photography, who attached great importance to the strength of the pyro in development, and advocated, with certain plates, only a grain and a half to the ounce, a quantity which, with those plates, others failed in getting density. He was tackled on the subject, and proceeded to demonstrate. One plate was developed successfully, but not to the immediate discomfiture of his opponents. A second trial was proposed, and when his *estimated* "three grains" was shaken out of the bottle it was seized and weighed. It only weighed thirteen!

By the way, what constitutes the "American Standard" developer, and who appointed it a "standard?" Including Mr. Beer's repetition of the formula, and another English "translation" of it, I have quite recently come across four versions of it, all, I think, different. Certainly two versions, published by two different American societies, looked very much like two distinct standards.

The stale old outdoor meeting joke of "developing a goodly number of plates (of ham and eggs)" cropped up again the other day for the enlightenment of the members of the Derby Society. The original perpetrator might have been excused, not only on the ground of novelty but also of greater logical exactitude. His joke was about *cleaning* plates. But the modern plagiarist's intellect does not rise to correctness even. Development is a constructive operation; the manipulation of a plate of ham and eggs decidedly destructive, so far as what is on the plate goes.

Mr. W. T. Wilkinson's application of the "air brush" (how I dislike that name! so suggestive of a Cockney's way of speaking of a different implement) to photo-engraving is ingenious, and, I should think, would prove effective, giving, in skilful hands, a superior grain, because selective, to that employed in the Klic process. As described to the members of the London and Provincial Association, his method consists in distributing over the plate to be engraved a fine spray of solution of bitumen so as to form a delicate grain. As the legitimate use of the air brush is for the shading of pictures in monochrome, it is easy to imagine that it will serve its new purpose well, and be capable of producing a variety of "grains" to suit different subjects. The plate is afterwards etched through a carbon print developed on the plate over its artificial grain.

This reminds me of a similar application of a ruder instrument I saw some dozen or more years ago. A young artist, a friend of mine, who did a good deal of work in drawing portraits on the litho stone, was at the time I speak of making his first experiments in etching on zinc as a substitute for the stone, and what chiefly bothered him was getting a satisfactory grain. He had tried a variety of plans he had heard or read of, but none satisfied him. One day, as I stood watching him at work, and listened to his growls about the grain, I suggested, "Why not shade the zinc as you do the stone?" "By Jove!" he said, "the very thing." His method of shading was to charge a tooth brush with thin litho ink and with the finger to "spirt" it on to the stone in the same manner that "falling snow" is put into negatives by artful photographers. My friend may still use the same process, for he has been engaged on "process" work for many years now.

Mr. Cowan's method of producing a chemically clean surface upon glass communicated to the same meeting is worth knowing, and though not perhaps of very wide utility, may be found invaluable on special occasions. For instance, in silvering reflectors or small mirrors the difficulty usually is to get a perfectly clean surface, and this plan appears to fill the want. It consists in coating the glass after ordinary cleaning with a solution of gutta-percha, which, when dry, is stripped off the plate, leaving an absolutely clean surface.

From what I can gather from the discussion that followed the reading of Mr. Octavius Smith's paper, *On Systems of Numbering Photographic Lenses and Diaphragms* at the North London Society, that gentleman took the trouble to go with unnecessary accuracy into figures and details that were of no real practical value. Mr. George Smith (there seems to be an epidemic of Smiths amongst lenses and diaphragms) got up and corrected the other Mr. Smith on one or two points, and advocated practical in preference to mathematical accuracy. There was a sly sarcasm in Mr. Mackie's allusion to the manner in which the other Mr. Smith had "endeavoured" to be "extremely accurate" in placing himself in a mathematical position to be able to guess at the rapidity of his plate and the value of the light. But Mr. F. W. Hart pleased me most in his remarks. In his early days at photography—the early days of photography, in fact—there was no trouble about exposure tables and diaphragm numbers; they trusted to experience, *i.e.*, common sense. "It was only within the last few years that photographers had commenced to worry themselves about such matters." And he finished by advising that to learn experience would serve the young photographer much better than all the "tables."

My own experience with tables and calculations is similar to Mr. Medland's; they are more bother than they are worth, and utterly misleading if implicitly trusted to. As for "Mr. Medland's friend," who was stated by another member to produce "excellent work with the aid of exposure tables," I should be inclined to say he did it with the aid of experience, and in spite of the tables.

I once had, on a photographic trip, to share a double-bedded room with a travelling companion, one of the mathematical-before-photographic class. He had been at work all day with his tables, and had littered the landscape with the crumpled papers on which he had performed his calculations, even "composing" his pictures with a funny looking instrument of his own invention. After we got into bed he went into the theory of things in general, and by about daylight seemed to be making things clear to himself, when I dozed off and dreamt that I was the late Mr. Babbage's calculating machine, and not

COLOURING AS APPLIED TO PHOTOGRAPHY.*

As laid down, all colours *complementary* to each other are greatly enhanced in value and effect by their being judiciously placed in juxtaposition one with the other. Indeed, the general harmony of a picture may be said to altogether depend upon this principle being strictly adhered to. Colours, however, which are *not* complementary to each other when so placed will mutually injure each other's natural beauty. For example, a blue and a purple placed in close proximity will be mutually injured, and this for reasons very easy to discover—the natural purity of each tint being marred by its companion. The blue will be found to assume a somewhat greenish tint, resulting from the yellow rays emitted by the purple, and the purple in turn assuming somewhat of a russet tinge on account of the orange rays given out by the blue.

In the case of *neutral tints* being placed in contact with full hues or tints, these same neutral tints should incline to the complementary of such hues or tints, as the best and most harmonious effects can only be produced by so doing. Thus, when an olive tint is placed in contact with a yellow, it should, in order to produce the best effect, incline to purple rather than to green, the former being the complementary of yellow.

In this regard, the contrast of hue or tint is not the only point to be considered. There is also the contrast of intensity, and much effect at times may be gained by its skilful treatment. It will be easily observed that when two tints of the same colour, but of widely different degrees of intensity, are placed together, the deep tint will appear to deepen still more in tone, while the light tint will seem to become still lighter, the difference in intensity being most observable at the points of contact. This principle will hold good in contrasting colours of varying degrees of intensity, inasmuch as they will be found to receive a double modification by being brought into contact—the brilliancy of hue as before stated as well as the intensity—the deepest colour seeming to be still deeper, while the least intense will appear to become more washy.

All colours when brought in contact with pure white gain depth, for the simple reason that the white assumes the complementary tint of the colour near it. On the other hand, black has the effect of weakening the colours placed in contact with it, or even in its immediate neighbourhood. There is a wide difference, however, produced by the various hues coming in contact with or on black, the depth of black being very greatly influenced and materially modified by contact with such colours as have a luminous complementary. Thus, when purple comes in contact with black, the latter loses its depth and brilliancy considerably, owing to the tinge imparted to it by the yellow rays emitted by the purple; should it come in contact with blue or green, it will partake of a rusty tone, caused by the orange or red rays thrown out by these colours. On the other hand, black, when coming in contact with red, yellow, or orange, becomes more intensified. All pure colours will be found to gain brilliancy by the juxtaposition of grey, which may be considered a mixture of black and white.

The harmony produced by the skilful placing in juxtaposition of such colours as mutually benefit each other, and the harmony produced by judicious contrast, are not the only harmonies we have to consider. We have still what may be called the harmony of analogy. This latter is to be obtained by a combination of the various gradations of any one colour in its own scale, or of the hues and tints in the order in which we may observe them in the solar spectrum.

By the judicious arrangement of analogous tints in their most favourable and harmonious relations and almost endless variety, the most pleasing results may be secured. In this treatment, however, there are more difficulties to combat with than either of the other two. The effects are less striking—more delicate, as it were—and require a greater amount of real artistic feeling and keen perception, combined with more skilful management, to produce really happy and successful effects.

The laws which regulate harmonious colouring are *not* the outcome of an over-excited fancy, or even the result of some extremely sensitive organization, which, being endowed with a keen appreciation of the beautiful, has laid these rules down to be followed by less gifted followers. On the contrary, this harmony is inherent in nature, and

* Continued from page 518.

it is nature herself which lays down these laws for our guidance when we would seek to reproduce her. It will require but a small amount of study or observation of nature to discover ample and pleasing illustrations of the various kinds of harmony. What a striking illustration of the harmony of analogy does the rainbow afford us, with all its beautifully blended and delicately graduated colours! If by any chance this most wonderful study of colour should not have received ample attention from any reader, let me suggest that the next opportunity be taken advantage of. I cannot think of any combination so complete and so thoroughly showing the balance as well as the harmonies of the various colours.

All the principles to be learned from such observations are of the greatest value to the art student, and should never be neglected, whether his intention is to follow landscape painting or portraiture. Although of greater value, perhaps, in the former branch of art, it will be found to be of very considerable help in the latter, and in all cases will exalt the artistic feeling of the student.

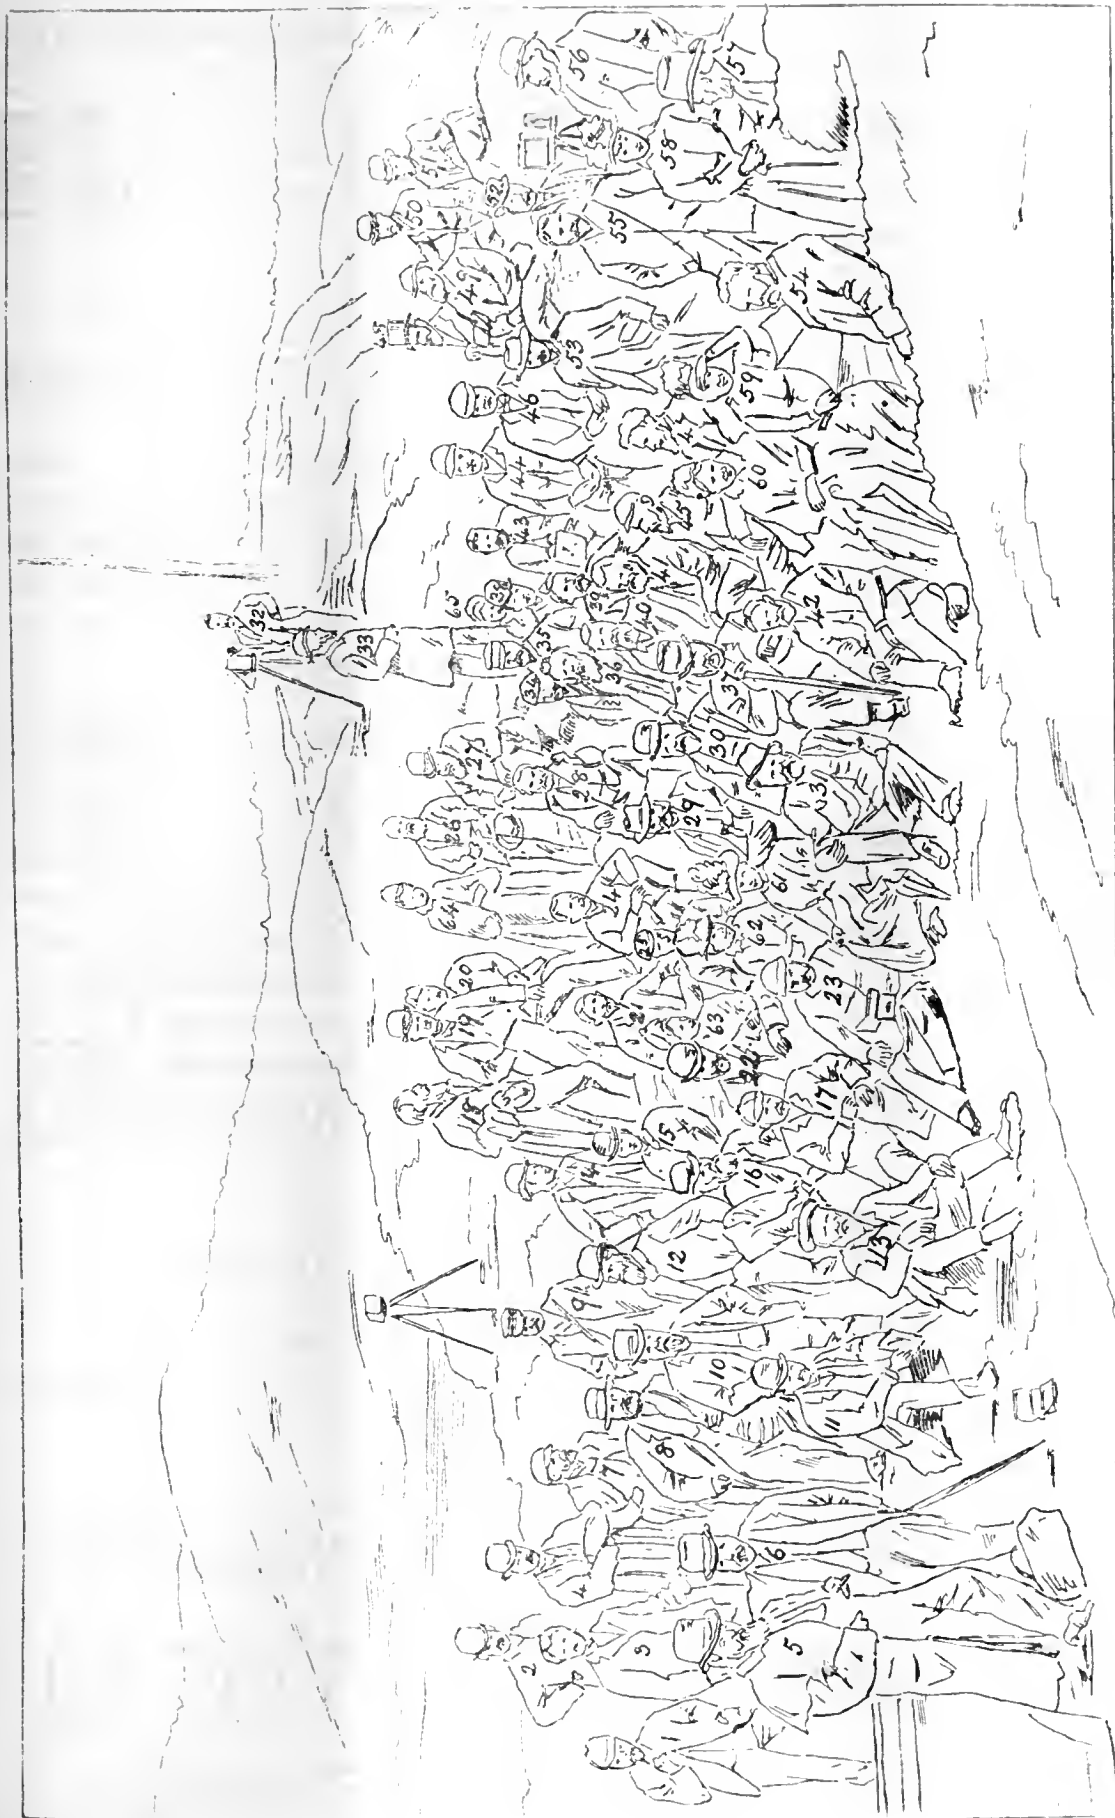

What a lesson is to be gained from the careful contemplation of almost any landscape. There we may observe the blue of the extreme distance blending with the cool greens and greys of the middle distance; then these in turn seem to melt into the warmer and more positive greens, yellows, and browns of the foreground. If on such a landscape we have the advantage of a setting sun, how completely changed, and still more beautiful, is the effect. There is a warm glow thrown over the whole scene; every object seems to be beautified as it were by a golden light and a purple shadow. Nature will afford the willing and observant student endless varieties of effects to study from. In nature harmonies of contrast are not hard to find, they are visible at every step; from the wild moor to the fertile valley everything suggests beauty and harmony. The ever varying of yellow gorse mingling with the purple heather, the scarlet holly berry and its deep (and complementary) green foliage, the rose of whatever hue and its green leaf in harmonising contrast.

The wildest dreams of an artist will never suggest anything like the incredible freaks of nature as regards drawing as well as colouring. Gustave Doré produced some very extraordinary effects in the way of clouds—studies which really appeared absurd on account of their seeming extravagance, and to tell the truth I myself thought them *impossible*. But on examination I felt assured that they were the products not of a wild and fertile brain but of a close study of nature. The autumn of the year I saw them I saw almost every evening the most extraordinary forms and combinations of clouds I ever saw in my life. In fact I never saw anything like them since. They were to be seen from Piccadilly looking over the Green Park. Once going by boat, too, from Dublin to Holyhead I had a look at the Welsh mountains in the early morning. I never saw such colouring, and I am sure if transferred to canvas few would be found to believe it real and as in nature. It is many years now since this occurred, but it so fixed itself in my mind I have never forgotten it.

From all this the grand inference to be drawn is—study—study nature, for she is the only fountain of real knowledge. The principles laid down here are only those dictated by nature. They should be properly understood by all as they will enable the colourist, while preserving truthfulness to nature in such points and details as are absolutely inherent in the *original*, to surmount the difficulties that may crop up in the management of the draperies, accessories, background, &c., thus giving due value to the complexion, and producing not only a pleasing, but a perfect and harmonious picture.

There is much of all this which may not appear necessary, strictly, to "colour as applied to photography," inasmuch as colouring is mostly employed for portraiture in this line. But think what advantages it will give one in the treatment of a picture to have a thorough knowledge of the art generally to support you. How much more easily will you gain your effects, and how much more harmonious and artistic will be your picture when finished. How often can an ungainly figure be made presentable by the artistic treatment of the surroundings.

Another advantage that may be gained by a thorough knowledge of the principles of colouring is breadth. An experience I had a few years ago will, I think, explain this view satisfactorily. I had an order for two portraits, which had to be finished by a certain date; I could not possibly get them done myself so I was obliged to give

NOW IN COURSE OF PREPARATION.

The British Journal Photographic Almanac

AND

PHOTOGRAPHERS' DAILY COMPANION for 1888.

EDITED BY J. TRAILL TAYLOR.

Owing to the increasing and unprecedented success of this useful "ANNUAL," it is the intention of the Publishers to print of the Forthcoming Issue

20,000

THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1888

is now in course of preparation, and it is intended not only to publish it at an earlier date than usual this year, but also to extend its sphere of usefulness. It is needless to expatiate upon the value of THE ALMANAC to those who practise the art in any of its branches. Suffice it to say, that its character as a concise summary of the doings of the past year almost compels its presence in every studio and laboratory throughout Great Britain and her Colonies, as well as in America and on the Continent, where it is as well known and appreciated as at home.

Advertisements inserted in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC

are, therefore, sure to secure a wide and lasting publicity.

The Publishers beg to intimate that priority of position will be given to Advertisements according to the date of receipt of order. It is not imperative that the copy of the Advertisement should accompany the order for space in the first instance; but, in order to have priority of position, it is absolutely necessary that the order for the retention of space should reach the Publishers at the earliest possible moment.

The CHARGE FOR ADVERTISEMENTS in the ordinary pages is as follows:—

WHOLE PAGE, 63s. | HALF PAGE, 35s. | QUARTER PAGE, 20s.

The Pages on the Cover, and a few others of great prominence, will be charged by Special Agreement.

SPECIAL ATTENTION IS GIVEN to the DISPLAY OF ADVERTISEMENTS, so as to render them Attractive.

SHOULD you desire to insert any advertisement in the forthcoming issue of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, an order in course of post will be esteemed by

H. GREENWOOD & CO., Publishers, 2 York Street, Covent Garden, London, W.C.

them to a friend. He made a great success with them, *although he never saw the originals*. I had not three hours work to finish them, although this may seem impossible to many. (Please note, however, they would not be mistaken for the work of Sir Thomas Lawrence or Sir Joshua Reynolds.) However, to get back to the pictures. By some strange accident he painted the backgrounds differently, so differently, indeed, that the pictures did not look the same size. In fact, you could measure the canvas and then go back, and you would still hold that they were not the same size. One treatment dwarfed the canvas, while the other gave the feeling of breadth. When I drew his attention to it, he altered the defective one and made a most successful pair of portraits. It was a pure oversight that let him make such a mistake.

This will show, however, that an artist who so well understands the principles of his art can produce on a certain size canvas an effect that will make it appear double the size and give it general importance. In art we need never be afraid of knowing too much, but rather always try to learn. I have had a fairly long experience in some ways, yet every day I try to learn, and I often find some strange experience crop up to repay me for my watchfulness and disposition to still learn.

REDMOND BARRETT.

(To be continued.)

METROPOLITAN INDUSTRIES.

THE GOLD AND SILVER WORKS OF R. PRINGLE & CO., AND THE REDUCTION OF PHOTOGRAPHERS' WASTES.

FROM the fact of so little being said at our various photographic societies concerning the economies of the art so far as regards the utilisation of wastes, one is tempted to ask, Are photographers really aware what an enormous saving of the noble metals—silver in particular—may be effected by the extremely simple system of preserving their wastes, and sending them to the refiner or reducer, and having them converted into current coin? We know of one photographer who makes somewhat of a hobby of reducing his wastes himself, and who thinks he does his work ineffectively when he fails to recover seventy per cent. of the silver employed in sensitising his paper.

We once arrested the hand of an amateur who was just about to empty down the sink the contents of a large dish of hyposulphite of soda in which he had been fixing 15×12 negatives until, as he said, it had become so saturated that it had lost its power for fixing any more. It was, instead of being allowed to run to waste, transferred to a glass vessel, and a lump of potassium sulphide (liver of sulphur), previously dissolved in water, was poured in. This act was attended by the production of a copious black precipitate, representing the whole of the silver that had been in all the plates fixed in that bath, except so much as had been reduced by the developer and gone to form the image—a somewhat small proportion. Now we are not here going to give a dissertation on reducing wastes, but we may say that the precipitate referred to could either be converted into nitrate of silver, melted into a nugget of the pure metal, or, easier still, be sent to the refiner, who would return its value in cash to the sender or charge him a small sum for reducing and melting it down in a bar.

All this is by way of preface to a brief account we purpose giving of a visit we paid to one of our metropolitan silver and gold refineries—that of Messrs. R. Pringle & Co., Clerkenwell-road, better known years ago as the famous Wilderness-row of the jewellery and watch-making district of London. Indeed, Mr. Pringle still keeps up the old associations connected with that once well-known name by designating his factory the "Wilderness Works."

After entering, and passing by the jewellery sale department as possessing no interest in our present quest, we descended into the basement storey, which extends out behind, and where the refining is carried on. In one place we saw a huge stamper—a species of steam hammer—alternately raised by steam and falling by its own gravity in a mortar, where it was engaged in crushing to a fine powder crucibles and skittle pots, which, having done their duty in melting the noble metals, were being prepared for a further yielding up of every atom of these metals which had remained attached by adhesion or permeation.

In another place we saw a boy subjecting to a searching examina-

tion the sweepings of some jewellers' floors or benches, opening every scrap of paper carefully, for who knows that lurking therein may be some diamond, ruby, or gold ring which might have been lost, and which would be destroyed in the crucibles to which a transference was so soon to be effected.

Photographers' wastes were there in various forms, much of it in the shape of ashes, implying a previous state of existence in the form of paper or cloths. When a parcel of waste is received from a photographer it is reduced to a homogeneous mass, and a definite and carefully weighed portion placed along with a flux in one of a series of tiny crucibles kept for the purpose, and through the agency of furnaces, each capable of holding several of these, a bead of metal is obtained which, when placed in the assay balance, enables the assayer to determine with a singular degree of accuracy the value of the whole.

The reduction of the wastes is effected by a series of large crucibles in furnaces at the end of the building. Of course it must not be imagined that photographic wastes alone supply these furnaces and refineries with work, for although it has a somewhat unpretending exterior, yet is the interior a hive of industry, embracing everything connected with the metallurgy and working of the gold and silver trade, established over fifty years ago, and now employing altogether about seventy hands. During our brief visit we witnessed the melting of metals and their being cast into ingots, rolled into sheets, and drawn into wires.

It may be mentioned that two members of the firm are amateur photographers, therefore they have the advantage of knowing exactly what the requirements of the photographic profession are.

The preparation of nitrate of silver and chloride of gold, goldsmiths' and silversmiths' work, mounting, polishing, electroplating, and gilding, is also extensively carried on, altogether consuming large quantities of gold and silver, so that Messrs. Pringle are only too glad to allow the utmost value for the precious metals in order to keep up their own supply.

PHOTOGRAPHY IN COLOURS.

ONE of the first communications I ever addressed to any journal was on *Photography in Colours*. It is dated "London, May 19th, 1865," and appeared in *THE BRITISH JOURNAL OF PHOTOGRAPHY* on the 26th of the month which I have named. I was at that time in the employment of Mr. J. R. Johnson, of the "Pantaseopic Company," and at their establishment, No. 3, Red Lion-square, W.C., my duties were those of an operator, chemist, and so forth. My various predecessors, when their silver baths went wrong (a very common thing in 1865), were in the habit of bottling them up, labelling them "old bath," and proceeding to make a new one. I accordingly inherited several gallons of "old bath," which Mr. Johnson required me as a chemist to reduce to a working state. I accordingly mixed the lot together, sunned them, and evaporated down to crystals. Some of the baths, I was informed, contained acetate of soda, some citrate, and sundry similar bodies added to gain intensity. However, the new bath mixture, duly filtered and acidified, worked extremely well, with this very startling peculiarity, that the photographs taken *were all in colours*—natural colours when seen by reflected light, their complementary ones when seen by light transmitted. The colours were not bright and vivid, but they were *there*, on every negative, and were not discovered until the fixing and washing had been done, nor, indeed, until some weeks after varnishing.

Red Lion-square, the subject of my negatives, which were taken for the verification of the Grubb's numbers of the aplanatic lenses which we used, is not—or at any rate was not—a place of lively colours. The red-brick houses had been rendered dark and dingy by the hand of Time; the green of the garden trees and grass was but "indifferent honest," and the blueness of a London sky was generally of a sombre hue.

Carefully inspecting one of a number of these negatives, I was struck first by the fact of its presenting, when viewed askew, a murky effect, as of a coal-tar stain floating on the inky waters of the Irwell (the river of my native city). There was a very dirty blueness spreading over half the negative. I next observed that this murky blueness was on the sky alone: then that the trees and grass were a dirty, murky green: then that the houses were a filthy brown. By transmitted light the filthy complements of the filthy colours were distinctly seen. The appearance was on all the negatives. I showed them to Mr. Johnson, and when told they were made with

the old baths revived, he ordered a careful analysis of the material of the baths; but I detected nothing definitely but silver, soda, potash, and nitric, acetic, and citric acids. The mixture previous to treatment smelt of aldehyde, and after crystallisation and re-solution of apples. What the substance is which smells like apples I don't pretend to know, but I remember a fellow-student in the laboratory of Owens College was once unfortunate enough to upset about fifty shillings' worth of bichloride of platinum which he had made upon the laboratory table where we worked. We mopped it up with filter paper, washed out the paper, and evaporated the solution down to dryness over a water bath, and that smelt like apples, too. New baths were made, and citrates, acetates, and formates added, but no filthy colours were obtained. The results were merely normal, but with a rich peculiar bloom. One of these negatives, with Mr. Johnson's sanction, I retained, and it is possible I may find it yet, though quite twenty years have elapsed since I saw it last. These pictures were photographs in colours, feeble and smudged almost out of sight by the overwhelming preponderance of the ordinary negative deposit.

I can give no further particulars of their production than that Mr. Johnson's dark room was dark indeed. It was a photographic tent with ruby glass about nine inches square, and a yellow textile flap besides. It was, further, situated far from the window of the room, and so dark that it was barely within the reach of possibility to see what you were doing. It was the production of these negatives which led me to give consideration to the subject of "photography in colours," and to write the letter which appeared in your issue of May 26, 1865. That letter is concluded by the paragraph:—

"However, I quite believe, from such evidences as have fallen in my way" (alluding to those described above), "that by carefully, patiently, and perseveringly pursuing a systematic course of experiments, recording and remembering their results, we shall at length be enabled to solve the beautiful but difficult problem of *Photography in Colours*."

In the body of my letter (that of 1865) I say:—

"If we could prepare a plate which would be acted upon by rays of all colours . . . it is perfectly obvious that it must be prepared and retained in absolute, and not relative, darkness before it receives the intended exposure, unless the process is to be an extremely slow one."

Again, I say:—

"We must either discover a means of destroying the sensitiveness of the film, without destroying the latent image or our capability of developing it, or else the latter process must be conducted in absolute darkness also."

"By what means sensitiveness of the film might be destroyed before development," I continue, "is really far beyond me to suggest. To develop in absolute darkness (if we would have other than random successes) we must evidently have some means of knowing when to stop apart from the use of our eyes. These means, beyond doubt, will consist in having such a knowledge of our plate and its properties, the amount of light, and the action of our subsequent chemical reagents, as will enable us to perform all our operations to time. To ascertain the exact properties of our sensitised plate would require careful experiments to be conducted, with a prior and thorough knowledge of the composition, &c., of our chemicals, and with the aid of a variety of instruments, amongst which there would certainly be a thermometer, probably a barometer and a hygroscope, and possibly an electrometer and a host of others. To ascertain the amount of light . . . we certainly require photometrical apparatus, probably very different from any now in use; whilst to acquire a knowledge of the actions of our subsequent chemical reagents would require experiments carefully conducted with the combined knowledge of our plate and light."

So said I, and in these columns, two-and-twenty years ago, and with very little variation so say I now.

I do not now think the barometer, the hygroscope, or the electrometer would be required, whilst as to photometrical appliances I am of opinion that those produced since then by others and by myself would answer all the purposes required.

When staying in London in 1881 I spent a considerable portion of five weeks in the laboratory of Captain Abney at South Kensington, and was there shown some of his spectrum photographs in colours on silver plates. Probably I did not see the best examples. Those I did see, however, whilst they showed all the colours, did not (considering the character of the objects photographed) present much less of smudginess than my own of 1865. There was, however, this great difference—Captain Abney knows how his own were got sufficiently well to get them when he likes again, whilst my own results I am unable to reproduce at will.

I think, however, Mr. Carey Lea's researches are likely to set us on the track again, and I still am confident that "we shall at length be enabled to solve the beautiful but difficult problem of photography in colours,"

D. WINSTANLEY.

THE CAMERA IN THE FIELD.

THE tourist season has set in with its usual severity: moor and mountain, wood and stream, are being daily stormed by the silent artillery of the optician, and photographers in search of the picturesque are as common as shells on the seashore. The late descent upon Glasgow and the Clyde suggests some novel reflections. Some day, for instance, we may read that the "Saucy Susan," seventy cameras, was passed in such and such a latitude and longitude; or that Slocum-in-the-Slush is at present invested by the Hotchkissian battery of a hundred and forty cameras, mounting instantaneous shutters with a range of speed from a second to the ten thousandth part thereof. Parenthetically, another fantastic avenue of thought is opened up by the frequent spectacle of printing frames placed in the windows of private dwellings. The eligibility of a suburban villa must be appreciably enhanced if its front windows enjoy a moiety of sunshine, so that gentlemen's negatives may be printed before leaving for the City. No enterprising dealer has yet annexed the notion of retailing complete sets on the hire purchase system; but it is evident that before long certain dwelling houses will be mentally ticked by those who are amateur photographers and those who are not, according to their sympathies, just as now one remarks, responsive to his feelings towards that ill-used instrument, the presence or the absence of a pianoforte.

Those who are turning their backs upon the populous city pent are to be envied. In company with the grand old gardener and his wife in the great Miltonic epic, the world is all before them, and there is little doubt that full advantage is being taken of so wide a choice, and that when October comes round the operations of development and printing, for which the month of brown ale and nuts is noteworthy, will be the chief concerns of an expanding circle. It is in the field that the qualities of the modern landscape camera are put to the only satisfactory test, and that we find out the true value of paper theories and shop-counter nostrums. Students of these columns will not have failed to notice that whilst one authority recommends an instrument because it possesses all the "latest" improvements, another denounces it on account of its faddishness. In fact a bitter duel is in progress between the ideally perfect and the simple but practically efficacious. Of late there has been a strong tendency to supplement the chief functions of the landscape camera by a host of ingenious but superfluous movements. Now it is easy to go too far in the direction of florid "improvements" when devising a new camera, just as in architecture an otherwise beautiful façade may be marred by too much ornamentation. In this connection simplicity is almost synonymous with efficiency. The new race of patent cameras are certainly not simple, and many of their movements are—if a camera can be accused of any latent waggishness—absurdly funny; more, they are not only unnecessary, but they defeat their own object by taking longer to work than the very methods they are supposed to supplant, and, in the case of entirely new devices, are not wanted once in a blue moon. If a camera is made of well-seasoned wood, and by hand; light, without being flimsy; portable, at no sacrifice of freedom of play; with a rising, falling, and sliding front; a reversing holder; double swing; and a good length of focus, every possible requirement of all but the superline virtuoso will have been provided for. These patent movements will not stand the very easy test of constant usage. For example, revolving backs are uncertain in their action, and their advantages are imaginary, for the reversible holder is simpler, more reliable, and often quite as quick in practice. Again, the turntable as an integral portion of the baseboard possibly saves a second or two, but I believe it to be an ultimate source of weakness to the camera, for whilst the time-honoured triangle causes no structural strain to the instrument it supports, in the case of the "feather weights" now in favour the diverging pressure of a powerful tripod must tell in the end. Despite the ingenuity of some of the recent improvements, I do not think they are destined to win much applause. At the present rate, the patent camera of ten years hence will be an awful thing to comprehend, especially to a novice. It is bad enough now, even if all the movements work as smoothly as it is claimed they do. The other day one of these clever concoctions was forwarded to its purchaser, who had to use brute force to get one of the patent movements to fulfil its task, whilst, horrible to tell, he had to open the dark slides with a chisel, for the clasps were hammered down quite a sixteenth into the wood. They manage these things better in the vicinity of Clerkenwell and Gray's Inn-road, where innovation is slow but successful.

I always follow the patent news week by week, as it is generally instructive, and sometimes amusing. For one thing, it fills me with astonishment at the tremendous fecundity of the photographic "inventor." I wonder how many times it stands recorded that So-and-so has applied for letters patent for improvements in instan-

taneous shutters; that Tom, Dick, or Harry, has made a similar request in connection with the camera; and that Mister Tout le Monde has humbly prayed for ditto ditto for a new tripod stand? This sort of thing has been going on for years with almost grotesque persistency, and yet to-day, if we could take a plebiscite, I believe we should find that the plain drop shutter with an elastic accelerator is the best for all-round use; that the camera I have sketched (which, minus the reversing holder, was known a decade since) is not likely to be displaced; and that the simple folding tripod, which is relatively as old as the hills, is almost as firm in popular favour. Our inventors should diffuse their energies. Why won't somebody give us a dark slide, [which, by ready adjustments, will carry plates of every size below its maximum capacity, and thus obviate the troublesome inner frame? I never look at one of these heavily patented cameras without thinking of the moral metaphor wherein figureth a camel and a gnat. What is the use of a hundred adjustments to the camera if the slides are not absolutely, unimpeachably light-tight? It will read strangely, no doubt, but actual experience proves that for every ten men who make a good camera not more than one turns out a reliable dark slide. So much for machine-made apparatus. As Thackeray's Jeames remarks, "Oh, trumpetry! oh, Moses!"

Some people think that the size of the small numerals on their slides might be increased with good results. It was a practical man, and not, I should imagine, wholly unconnected with the tea trade, who had the numbers of his slides painted on them to the size and appearance of the fat figures one sees on the caddies in the grocers' shops. The resource of the young lady who went to Egypt with her camera was scarcely so happy. Having focussed her first picture to the requisite sharpness, she gave orders to have the screen, which was a moveable one, packed away, and instructions that the camera was not to be touched on any account. "For," to quote the fair innocent, "I've got a good focus, and I mean to keep to it." So she did; roaming Pharaoh-land, and exposing dozens of plates upon as many objects, near and far, big and little, with a light heart and a "good focus." And when she came home and had her plates developed, and scrutinised the results, she—well, she emulated the parrot of revered memory. A collection of all the photographic oddities one hears of would form a droll book. An absent-minded man "took up" with photography and on his first outing forgot to remove the cap; on the next, took it off before pulling out the shutter of the slide; on the next, solemnly exposed the plateless slide for five seconds with $\frac{1}{2}$; and ended by offering his kit for sale. He didn't find a purchaser, and after a time he began to wonder if the non-utilisation of his brains had anything to do with his failures. I don't know what conclusion he arrived at, but he is now, or was recently, passably proficient in the art he was once heard to stigmatise as too difficult for him.

MARSTON MOORE.

MAGNESIUM COMPOUNDS FOR FLASHING LIGHTS.

RECENTLY in a note appended to our reprint of a patent, it was pointed out that the use of a mixture of powdered magnesium, sulphur, and sulphide of antimony, to give flashing lights for photographic purposes, is a very old invention, seeing that it was prominently brought before the South London Photographic Society on November 9, 1865, by J. Traill Taylor, and formed the subject of an editorial article in *THE BRITISH JOURNAL OF PHOTOGRAPHY* in the following year. But its utility seems now to be on the point of being appreciated, for its merits are being fully investigated in Germany. It seems likely to have considerable commercial value in photographing sitters in their own homes; it may make this class of work common.

At one of the meetings of the Berlin Society for the Advancement of Photography, with Dr. Vogel, the President, in the chair, Herr Miethe gave particulars relating to some experiments he had made in company with Herr Gædicke concerning instantaneous photography by the magnesium light. The *Photographische Mittheilungen* states that he mentioned that they had worked for six months at the experiments in order to render the method of practical utility; they abandoned the use of magnesium riband and replaced it with the powdered metal mixed with salts rich in oxygen, but until recently they did not obtain satisfactory results in photographing moving objects. Herr Kuntze, who assisted them in their researches, said that the final results were surprising, and exhibited some pictures they had taken, including one of a dog, which proved the rapidity attained. Another print was from a negative of an old painting, and was a well-balanced monochromatic reproduction; in this case, salts which coloured flames red and yellow had been added to the powdered mixture. Herr Schultze-Hencke remarked that one of the portraits had been taken by daylight, and the part which was in shadow by the light of day alone, had become the brightest under the influence of the

magnesium light, consequently plenty of illumination was afforded by the method. The meeting considered the invention to be of high value.

Herr Gædicke then gave a practical demonstration, by taking the portrait of Herr Milster. The mixture was placed in a lantern with a glass face, that the smoke might not escape into the room. The shadow side of the sitter was illuminated by a reflector built up of tin plates, and too intense lighting of any part was avoided by the interposition of thin sheets of silk paper. To photograph a group, Herr Gædicke placed his mixture in a little iron cup, suspended by means of a cord before the luminous focus of a reflector made of leaves of paper. The lighting was graduated in the following manner:—Two or three thicknesses of silk paper were placed between the light and those nearest to it; the next part of the group had but one or two thicknesses of the paper interposed; upon the most distant part of the group the light fell direct.

The *Mittheilungen* then makes some statements which require additional verification. It says that the inflammable mixture has the following properties:—1. It contains powdered magnesium and a substance rich in oxygen; chlorate of potash, saltpetre, and sulphide of antimony answer the best. 2. This mixture does not disengage expansive gases; it cannot be inflamed by pressure or percussion. 3. It is therefore inoffensive. 4. It burns without detonating. The statement that it cannot be inflamed by pressure or percussion is difficult to believe, since most dangerous explosions have taken place with such a composition. Of course the materials must be ground separately and mixed gently, but even then, no matter how far the chlorate of potash may be diluted down, so to speak, with the two other substances, the statement that the mixture is safe against pressure and percussion is too serious, as well as too improbable, to be safely accepted on the authority of an anonymous newspaper paragraph.

The same journal goes on to state that the mixture can be used to give instantaneously any desired amount of light; the smoke is got rid of by burning the mixture in a lantern furnished with an open tube; the burning mixture chases before it the air contained in the lantern, but does not force its own smoke out; as the lantern cools, the products of combustion fall to the bottom thereof; the lantern can be cleared out afterwards by the aid of a bellows.

Next comes the use of the light in portraiture. To take instantaneous pictures it is necessary to use but one source of light. By making use of reflectors of silvered paper and screens of silk paper—probably thin oiled paper would answer—one has the power to produce lighting effects which will permit the taking of portraits anywhere, and that, too, instantaneously, which is an advantage; the flash lasts but from one-thirtieth to one-fiftieth of a second. This gives the following advantages:—(1), A better light during the dark days of winter; (2), sitters can be photographed in their own homes without difficulty; (3), children and animals can be readily photographed, no matter how much they may move about; (4), dark localities with persons in motion may be photographed; (5), by mixing in salts of lithium, barium, and so on, coloured pictures or objects may be well photographed.

Herr E. Vogel states that by the method he has photographed a group of six persons in a room of sombre colours, by the aid of two grammes of magnesium powder, with chlorate of potash added; the objective employed was an *aplanat* of Steinheil's, at a distance of 2·80 metres. All the members of the group gave a start when the light flashed upon them, but no effect was produced thereby upon the sensitive plate, which proves that the contraction of their muscles took place after the exposure. Herr H. W. Vogel has taken a group at eleven o'clock at night with a Steinheil *antiplanat*, not stopped down. The group consisted of from twelve to fourteen persons. Two and a half grammes of Gædicke's mixture, containing three-fourths of a gramme of magnesium, were employed, at a distance of two and a half metres. No reflector was used, yet the negative is full of detail. It is necessary to prevent the direct light from the flame entering the lens, otherwise the plate will be fogged.

A SEARCH FOR A SUBSTITUTE FOR HYPO.

[American Convention.]

ONE of the most useful discoveries ever made in the art of photography was the fact ascertained by Sir John Herschel in the year 1819, that solution of sodium hyposulphite dissolves the chloride, bromide, and iodide of silver. When we take into consideration that this salt, although now made in hundreds of tons every year, was then only a laboratory chemical, and very little used, we are surprised that Herschel should have thought of using it. But he did use it, and photographers ever since have blessed him; that is, they have done so if they got clean

prints. But in spite of the fact of the wonderful solubility of the silver haloids in sodium hyposulphite, there are numerous drawbacks to its use, and various other compounds have from time to time been suggested as substitutes for this universal fixer of plates and prints. Sir John Herschel used other solvents for the silver salts, notably ammonia and solution of common table salt.

Fox Talbot also used a strong solution of common salt. But these solvents never entirely dissolved the silver haloids from paper, and the white parts of the picture gradually acquired a blue colour, which, Talbot said, was not unpleasant, probably because he could not do any better. Robert Hunt kept some of these salt-fixed pictures for eight years, and found that they changed very little, except the blue tint acquired by the white portions.

In regard to the use of ammonia, it was found to be a good solvent for the silver haloids, but it also attacked the picture, and there was danger of destroying it completely.

Among other solvents used by the early workers in photography is potassium bromide, which was employed by Fox Talbot, and strongly recommended by him. Gustave le Gray, of Paris, used this solvent in a bath containing 360 grains in a pint and three-quarters, the fixing taking at least three-quarters of an hour; and he says it is better to wait two or three hours. Le Gray also mentions the addition of ammonia to the fixing bath of sodium hyposulphite, and recommends one fluid ounce to every quart of bath, which has a strength of about one in ten. He says this addition gives very pure whites; but the pictures were not permanent.

During the last year or two the question of using some other solvent for the silver haloids used in photography has again come up, and two substances have been tried—sodium sulphite by Captain Abney, and ammonia by a Scotch photographer, whose name has escaped me. In the case of the sulphite of sodium it was found to be too weak a solvent to use as a substitute for hyposulphite, although Captain Abney placed on record his work with it and made a table of its solvent power, which was published in the journals.

Thinking I might find something interesting in this question of the solubility of the silver haloids in various chemical solutions, I have made a number of experiments, which I desire to place on record. Although I have not been able to find a chemical compound that will supplant sodium hyposulphite in the fixing bath, yet I have experimented with materials that are solvents of the silver haloids, and this in no mean degree. In every scientific investigation the failures are often of as much importance as the successes, and with this idea in my mind I beg you will accept with charity this record of imperfect work done in the spare hours of a life that is full of engagements and calls to duty.

In the first place, I made a solution of silver nitrate of such a strength that one cubic centimetre of it would give 0.01830 gramme of silver bromide, 0.02290 gramme of silver iodide, or 0.01396 gramme of silver chloride, according as the precipitant was bromide, iodide, or chloride of an alkaline metal (potassium or sodium). To put this in other words, every hundred parts of the solution would give 1.830 parts of silver bromide, 2.290 parts of silver iodide, or 1.396 parts of silver chloride. The first series of experiments was with silver bromide.

Taking the solution of silver nitrate mentioned above, 25 cubic centimetres were used for each experiment and carefully precipitated with potassium bromide, so as to insure the least possible excess of the alkaline haloid. By this method there was secured a precipitate of silver bromide weighing 0.457 gramme (7.052 grains), which was carefully washed by decantation and drained from as much water as possible.

The first step was to find out how much of a given solution of sodium hyposulphite was necessary to dissolve this moist silver bromide under constant agitation. As the result of several experiments, it was found to require 8 cubic centimetres (about 2½ fluid drachms) of a solution of sodium hyposulphite containing 1 part of the salt in 6 of water, which is considered a fair strength for a fixing bath. This solubility of silver bromide means that in a bath of hypo 1 in 6, every part of silver bromide requires 2.9 parts of sodium hyposulphite for its solution.

Taking the same quantity of silver solution and producing the silver bromide in the same manner as mentioned before, the solvent action of ammonia was examined. The ammonia solution had a specific gravity of 0.97, and contained about 7 per cent. of ammonia gas. This solution was used upon the silver bromide without any perceptible solvent action, even when used to the extent of three times the volume of the hyposulphite before mentioned. It appeared that this strength of ammonia was the greatest that could be conveniently used in practice, and, therefore, no further experiments were made with solutions of greater strength.

The next step was to see the effect of an addition of sodium hyposulphite to the above ammonia mixture containing the silver bromide still undissolved. On adding 4 cubic centimetres (about 1½ fluid drachms) of a solution of hyposulphite (1 in 3) complete solution took place. Hence, in presence of a 7 per cent. ammonia solution, 1 part silver bromide requires about 2.9 parts of sodium hyposulphite for its solution, an amount exactly the same as in the case of the sodium hyposulphite solution of a strength of 1 in 6 mentioned above. But it must be remembered that the amount of hyposulphite in the bath was only 1 in 21 of water. Therefore the presence of ammonia facilitates the solvent action of the hyposulphite.

A solution was now made by taking equal volumes of a hyposulphite

solution (1 in 3), and solution of ammonia of 0.96 specific gravity. This gives a fluid containing one-sixth of hyposulphite and 4.87 per cent. of ammonia. Using the same quantity of silver solution, the silver bromide being prepared as before stated, it required 4.5 cubic centimetres (about 1½ fluid drachms) of the mixture of hyposulphite and ammonia to dissolve 0.457 gramme (7.052 grains) of the silver haloid. This means that in presence of 4.87 per cent. of ammonia, one part of silver bromide requires 1.6 parts of sodium hyposulphite for solution. So that in the presence of ammonia a hyposulphite solution of the same strength will dissolve nearly twice as much silver bromide as in the case of one where the ammonia is absent.

Another mixture of ammonia and hyposulphite was now made to see the effect of diluting the bath with ammonia solution. One volume of a solution of hyposulphite (1 in 3) was diluted with three volumes of ammonia solution of 0.96 specific gravity. This gave a mixture containing one-twelfth of hyposulphite and 7.32 per cent. of ammonia. Of this solution the silver bromide, as used in the previous experiments, required 7.5 cubic centimetres (about 2¾ fluid drachms) for complete solution. Hence, one part of silver bromide requires 1.37 parts of hyposulphite for solution in presence of 7.32 per cent. of ammonia. But such a solution of ammonia is too strong to work with practically, and nothing further was done with it, except to keep a record of the experiment.

As the solution of ammonia is such a pungent liquid to work with, it was thought that perhaps some of its salts might be substituted for it. With this idea in view, a solution of ammonium carbonate was made containing 1 part of the carbonate in 10 of water. Equal volumes of this solution and sodium hyposulphite (1 in 3) were mixed and used upon the silver bromide prepared as before. The same quantity of silver bromide required 7 cubic centimetres (about 2 fluid drachms) of the mixture for complete solution. Hence one part of silver bromide requires 2.53 parts of hyposulphite for solution in presence of 5 per cent. of ammonium carbonate. We here see that there is but little gain in the use of the ammonium carbonate, and that it is not at all equivalent to ammonia.

Other salts of ammonium were suggested as possible solvents, and the chloride was next tried. A solution of sal ammoniac (ammonium chloride) was made containing 1 part of the salt in 10 of water. This was mixed with its own volume of hyposulphite solution (1 in 3), and used on the same quantity of silver bromide as in previous experiments, and prepared in exactly the same way. Of this mixture the silver haloid required 7.5 cubic centimetres for complete solution. This means that 1 part of silver bromide requires 2.73 parts of hyposulphite for solution in a bath containing 5 per cent. of ammonium chloride. Therefore the presence of ammonium chloride is no material gain as an addition to the hyposulphite bath.

One other salt of ammonium was available, and it was thought it might possibly prove useful; this was the acetate. To make this salt, ordinary acetic acid was taken and neutralised with strong ammonia. The solution thus obtained had a specific gravity of 1.055, and contained about 30 per cent. of ammonium acetate. One volume of this solution (which was slightly alkaline with ammonia), and one volume of hyposulphite of sodium solution (1 in 3), were mixed and used on the silver bromide as before. It required 6 cubic centimetres of this mixture to secure complete solution. Hence 1 part of silver bromide requires 2.2 parts of hyposulphite in presence of 15 per cent. of ammonium acetate. Comparing this with a solution of hyposulphite of the same strength (1 in 6), but without the ammonium acetate, we note a gain of solubility, but the large quantity of acetate necessary to secure it makes the mixture too expensive and not worth considering from a practical standpoint.

ARTHUR H. ELLIOTT, Ph.D., F.C.S.

(To be continued.)

Our Editorial Table.

A CONVENTION GROUP.

By JOHN STUART, 120, Buchanan-street, Glasgow.

THOSE of the members of the Convention who were posed on the rocks at Tarbert to have a group taken will remember among the numerous cameras erected on that occasion the very large one brought, with others of smaller dimensions, by Mr. John Stuart, of Glasgow, and which was the Triton among the minnows. That very excellent work was performed by this magnificent field-piece on that occasion we have for some time been aware, and the result is now before us.

The small-sized group which we issued a fortnight ago contained a goodly proportion of those who made up the party on the occasion referred to; but, in this large group, Mr. Stuart had been fortunately able to secure the presence of several who "made tracks" for their own cameras the instant the lens was capped, for there were many enticing subjects in the immediate vicinity, and the steamer by which the excursionists were to return was quickly expected to appear.

With a generosity which does him credit, Mr. Stuart, the artist, has placed his large group on the market at a price so low that no

one who desires to obtain a copy of this admirable group could possibly hesitate in securing it. The prices and details are to be found in our advertising columns.

The dimensions of this noble picture are 18×15 inches, and it is issued in two styles of printing, silver and platinotype. For an expenditure of from 3s. to 5s. 6d. photographers and photographic *cognoscenti* have it in their power to place on their walls a work of unsurpassed merit and interest. The individual figures of the group are large and distinct, and Mr. Stuart is entitled to the highest credit for having made such an excellent photograph, especially under the somewhat hurried conditions which prevailed at the time.

ILLUSTRATED CATALOGUE OF THE PHOTOGRAPHS IN THE NEWCASTLE JUBILEE EXHIBITION.

A SIXPENNY catalogue is no great feat in itself, but this one possesses special claims on our notice, for not only is it illustrated, but the illustrations are copious and printed in an admirable style. It contains not only the catalogue of the exhibition of photographs still open to inspection in the Newcastle Exhibition, but is embellished with a fairly large collection of the principal photographs in the exhibition. These are well printed, and, taken all in all, it is the cheapest sixpennyworth we have seen in connection with art photography. The publishers are R. Robinson & Co., printers and publishers, 56 to 66, Side, Newcastle-on-Tyne.

IMPROVEMENTS IN LENS SHUTTERS AND CAMERA FRONTS.

No. 12,238. JOHN EDWARD THORNTON, 3, New Lorne-street, Moss Side, Manchester.—*September 27, 1886.*

THE improvements which are the subject of this invention are threefold, and are hereinafter more definitely described, and have for their object, firstly, the construction of a lens shutter which can be made to operate and admit light through the lens to the sensitive plate in a photographic camera either instantaneously or for a lengthened period; and, secondly, to provide means to show or indicate outside whether the shutter is open or closed; and, thirdly, to reduce the number of loose parts and also the bulk by placing the shutter so as to work inside the camera front and behind the lens. In this case the shutter is always attached to the camera ready for use, and the usual cap may be used for exposing instead of the shutter, if desired, without detaching the said shutter from the camera.

In constructing a lens shutter according to my invention I form a box-shaped casing (hereinafter called the case), which may be made to fit on the hood of lens, as usual, or may be made to form part of the camera front (as hereinafter described), and having an aperture through the same for the passage of light. In the said case I insert two rollers working in suitable end bearings. One of the said rollers contains a spiral spring, and is hereinafter called the spring roller; this roller is provided at one end with a one-toothed ratchet and a spring catch to engage with the same, for the purpose of allowing extra tension to be put on roller when required, so as to cause the shutter to work quicker. The other roller (hereinafter called the winding roller) is provided at one end with a ratchet and pawl or catch, to prevent a reverse action of the said roller. A flexible blind of material impervious to light, and having a suitable-sized aperture therein to allow the passage of light, is attached by its two ends to the two rollers, so as to admit of being wound from off one roller on to the other.

When the blind is wound from off the spring roller on to the winding roller it causes the spiral spring to coil itself tighter and so put tension on the blind. When the pawl is thrown out of gear with the ratchet the blind, being released, winds itself back again on to the spring roller, and the aperture in blind allows light to pass through whilst it is passing across the lens.

In carrying out the first part of my invention I place on one end of the winding roller to which the ratchet is attached a small pinion, which is made to gear into a toothed wheel, which I call the detent wheel; the number of teeth on this wheel are so calculated that when the blind has partly wound on to the spring roller, and the aperture in the said blind has come opposite the lens, and the shutter is open, the said wheel shall have gone through one complete revolution.

Near the periphery of this said wheel a small stud or stop is fixed.

A lever, for the purpose of actuating the release, is pivoted to the side of case, and a small detent or stop is pivoted to this lever in such a manner that when the said detent is turned down it will come in the plane of the stud on detent wheel, and thereby arrest the motion of the said wheel after one revolution, and when turned over in the other direction it will be out of the plane of the stud, and so allow the free revolution of the said wheel. A spring pressing against the lever keeps it out of contact with the detent wheel until desired.

To set the shutter for an exposure the blind is wound on to the winding

roller and the pawl is put into gear with the ratchet to prevent its unwinding. If it is desired to give an exposure of short duration (commonly called instantaneous) the detent is turned over out of the way of the stud. The detent lever is so pivoted that when pressed the other end lifts up and throws the pawl out of gear with the ratchet on winding roller. The blind, thus released, instantly winds itself on to the spring roller, allowing the passage of light through the lens during the passage of the aperture in blind, and again closes the lens. If it be desired to give an exposure of longer duration the detent catch is turned over towards the detent wheel. When the lever is pressed down the detent is caused to come in the plane of the stud and the pawl is thrown out of gear, thus releasing the blind and causing the detent wheel to revolve. After one revolution of the said wheel the detent catches against the stud and so prevents the wheel from revolving any further, thus causing the shutter to remain open as long as the detent lever is pressed down. When the pressure is released the spring pressing against the said lever causes it to rise and allow a further revolution of the detent wheel, thus allowing the shutter to close. A stop spring operates against the pawl to prevent it falling into gear with the ratchet during a lengthened exposure, or any other suitable device may be used.

The usual pneumatic cylinder, piston, and ball, may be attached, if desired, for the purpose of actuating the detent lever in such a manner that the shutter will remain open as long as the ball is pressed and close when the pressure is released.

In carrying out the second part of this invention I attach a pinion to the detent wheel axle so as to revolve therewith; a toothed wheel is made to gear into this pinion, and the number of teeth are calculated so that this wheel shall make one revolution while the blind winds completely off one roller on to the other.

A pointer or index finger is attached to this wheel and indicates on a dial or plate whether the shutter is open or closed. By turning this wheel backward through one revolution the blind may be wound on to the winding roller more readily than by several turns of the said roller.

A brake for regulating the speed may be caused to operate against the indicating wheel, and may be adjusted by a screw, spring, or other suitable device.

In carrying out the third part of this invention I construct a camera front in the form of a shallow box or case, with an aperture through the same, and I place the shutter inside the said case so as to work behind the lens. To the back portion of this case the bellows are attached, and to the front portion the lens may be attached in the usual way or the ordinary lens panel inserted.

By inserting the shutter in a camera front, as described, the whole is more compact than when the shutter is in a separate case, and it does not interfere with the free use of the various parts of the camera.

In order not to unduly increase the thickness and bulk of the camera front and still make room for the rollers to work free, I make openings in the case to allow the rollers to partly project, and I cover the projecting parts each with a half tube or box-shaped covering, to make the whole light-tight; or the case may be thicker, if preferred, and the rollers placed entirely inside. The case may be made of wood, metal, or other suitable material, either wholly or in part combination.

I do not bind myself to any particular position of the parts, and the rollers may be placed in any convenient position, either horizontally or vertically.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

LAST Tuesday night, at a meeting of the above Society, held at 5A, Pall Mall East, London, Mr. William England, Vice-President, occupied the chair.

Mr. Friese Greene exhibited some photographs of the eclipse of the moon of August 3 last, taken by Mr. T. G. Gwilliam, F.R.A.S., and himself, with a Newtonian reflector six and five-eighths inches in diameter and six feet focal length: the exposures given were from a quarter of a second to eight or ten seconds. Mr. Greene next exhibited an instrument called the “phantoscope,” for projecting figures upon the screen, to which figures apparent motion could then be given.

After some general conversation the meeting broke up.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, on Thursday night, August 18, Mr. A. L. Henderson presided.

Mr. H. M. SMITH exhibited a Watson's new metallic developing tray, nickel plated, furnished with a bent lever arm for raising the plate at will. He stated that the Eastman Company had just brought out a new roller slide, so light that the slide, with enough paper for forty-eight whole-plate negatives, weighed but two and a quarter pounds.

Mr. J. J. BUGGISHAW said that the difficulty with roller slides is that before

developing only in about one case in ten is it possible to find out where to cut the paper; one way of doing it is to measure the paper from the starting point. Ordinarily it is not unusual for the operator to cut a picture in two.

Mr. E. G. Dornbusch exhibited some negatives developed after they had been wrapped in tissue paper and in old newspaper fragments outside the tissue paper; the printed matter appeared upon the negatives.

The CHAIRMAN remarked that in one of the plates the printing was "fuzzy," as if the newspaper had not been in close contact.

Mr. A. HADDON saw no reason why the effect should be prevented by the interposition of tissue paper.

The HON. SECRETARY said that the old question of what is the best method of packing plates when travelling seemed not yet to have been satisfactorily answered.

Mr. A. MACKIE responded that they should be packed face to face with nothing between, and each pair kept from sliding over each other by means of gummed paper at the corners.

Mr. WILLIAM ENGLAND stated that in some negatives sent to his son to print inequalities on the backs of the plates had produced images of themselves in the films.

Mr. A. COWAN said that the plates had evidently been packed in an unsafe light, and the inequalities had therefore produced a latent image of themselves through the glass.

The CHAIRMAN asked if any one present had photographed lightning flashes during the late storm.

Mr. J. TRAILL TAYLOR had heard of a photographer who had photographed a vase of flowers in his studio by the illumination afforded by successive flashes of lightning.

Mr. W. M. ASHMAN said that a developer containing sulphite of soda, recommended by Mr. Lincoln Adams in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, gave the best negatives he had ever seen; the formula was really worth trying.

The CHAIRMAN said that ammonia was best for very rapid plates, where density was required without frilling.

Mr. TAYLOR was of a different opinion, for with proper proportions of the carbonates of potash and soda density could be obtained, and the mixture answered equally well for paper and glass plates. Such a developer had been given by Mr. Wollaston at the Convention, and the speaker could strongly recommend it. It consisted of:—

Solution A.

Sulphite of soda	6 ounces.
Hot water	32 "
Make slightly acid with citric acid, and when cold add	
Pyrogallol	1 ounce.

Solution B.

Carbonate of soda	3 ounces.
Carbonate of potash	1 ounce.
Water	32 ounces.

To develop, mix equal parts of A and B, then add two parts of water. He often added double that quantity of water.

Mr. ENGLAND remarked that it bore much resemblance to Beach's formula.

The CHAIRMAN was of opinion that the more rapid the development the more brilliant was the picture, therefore he objected to the use of sulphite of soda.

Mr. TAYLOR had a batch of foreign plates which gave fog, and had no other plates available to expose upon a house they were pulling down opposite his office; how should he develop these plates without fog?

The CHAIRMAN said that before use the plates should have been exposed to sunlight, then treated with weak nitric acid and water in the dark; they would then have given unvelled negatives.

Mr. TAYLOR was aware of that, only in such cases he used hydrobromic acid, but in the one under consideration the exposures had already been made.

Mr. MACKIE thought that in such cases fog might be avoided by long exposure and very restrained developer.

Mr. TAYLOR responded that that also was his opinion, so he had given fifteen instead of two seconds' exposure to each plate; he should use the developer already mentioned, and when the image appeared would apply a restrainer freely. He thought of giving two minutes' exposure on the morrow, and applying an acid developer as in the old dry-plate days.

Mr. A. HADDON thought that one reason why sulphite of soda produced green fog was that it was a solvent of silver, so might tend to deposit finely divided silver all over the plate. Bromide of potassium was also a solvent of silver.

Mr. W. H. HARRISON thought it to be an open question whether green fog were not an organic dye.

Mr. AYRES wished to know the cause of the perishability of some photographic enamels.

The CHAIRMAN responded that they were perishable when dropped under a cart-wheel.

Mr. J. F. Pedsgrove was elected a member of the Association, and the proceedings closed.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

ON Tuesday, August 16, the ordinary meeting of this Society took place at Myddelton Hall, Islington.—Mr. A. Mackie, Vice-President, in the chair.

The minutes of the previous meeting having been read, Mr. MACKIE stated that at the previous meeting he said that Mr. Smith had been very accurate in his paper, not that he had attempted to be very accurate. With this correction the minutes were confirmed.

Several views taken at the recent excursions were shown by Mr. Higgins and others.

Mr. A. Liddle exhibited an example of pinhole photography.

Mr. E. Dunmore showed some curious crystals which had formed in a jar in which citrate of silver had been kept.

The HON. SECRETARY called attention to a formula for backing gelatine

plates which appeared recently in THE BRITISH JOURNAL OF PHOTOGRAPHY, and said that he had found it very easy to prepare and extremely useful in the prevention of halation.

Mr. DUNMORE said he always used burnt sienna and did not trouble to wash it off before developing his plates.

The CHAIRMAN then invited the members to continue the discussion upon Mr. Octavius Smith's paper *On Systems of Numbering Photographic Lenses and Diaphragms*, which had been adjourned from the previous meeting.

Mr. DUNMORE advocated the system adopted by the Photographic Society of Great Britain.

The HON. SECRETARY considered the discussion at the previous meeting turned upon the lines of experience *versus* exposure tables, instead of dealing, as he thought should have been the case, with the tables themselves and other aids to exposure. He agreed with those members who had previously spoken, that it was better to trust to one's experience than to trouble and perplex oneself with the many tables that had been compiled; but in the case of a person just commencing photography, and without an experienced friend at his side to assist him, he thought exposure tables were better than nothing at all to guide him in his difficulty.

The CHAIRMAN said it was necessary to have some system by which we could convey our ideas to other people, and whatever system was to be adopted should be an universal one—one easy to work and easy to apply. He was in favour of the system recommended by the Photographic Society of Great Britain.

Mr. DUNMORE said in ordinary landscape work he only used two stops, namely, $\frac{1}{2}$ and $\frac{1}{4}$.

Mr. GEORGE SMITH used six stops for his combination set of nine lenses. He thought Mr. Octavius Smith had adopted the main principles of the area system. The public hated figures, and, still more, formulæ. Mr. O. Smith was quite wrong in his application of the area system.

Mr. OCTAVIUS SMITH then proceeded to reply to the various arguments which had been brought up in the discussion. It appeared, he said, that one of the chief faults in this paper was its extreme accuracy. So far as the paper was theoretical he considered this point a great compliment, in the practical part, on the other hand, this extreme accuracy did not exist. Mr. Smith then proceeded to show, by reference to Mr. George Smith's published article on the area system, that the error which he had pointed out in his paper really did exist. In some cases it amounted to as much as one hundred per cent. With regard to a standard aperture, if $\frac{1}{8}$ were taken as the unit we should get as comparative exposure numbers many more fractional numbers than if we took $\frac{1}{4}$, and he thought that private ideas ought to be sacrificed to some extent for the sake of uniformity. The Photographic Society of Great Britain had carefully chosen a unit for the benefit of the photographic world in general, and, unless very good reason could be given for using another standard, it would, he was sure, be better to adopt theirs. The subject of experience *versus* exposure tables was, Mr. Smith thought, somewhat beside the question; it would be very foolish for any one knowing from experience the necessary exposure to use exposure tables. Mr. Smith mentioned two incidents which had by chance come under his notice during the past fortnight. A very experienced photographer who had just returned from a tour in the North had given all his plates about four times the proper exposure; another very successful worker, with over twenty years' experience, having focussed the interior of a church, exchanged the stop for one of half the area, and could hardly discover the difference in the illumination of the two images. In conclusion, he said that in making these remarks and in writing his paper it was not his object to prove that exposure tables were safer than experience or *vice versa*; he took for his standpoint this fact—that various systems of numbering stops existed, and the problem he had sought to solve was which is the best.

Excursions were arranged for August 27, to Oakleigh Park; and September 3, to Mill Hill.

The next meeting will take place on September 6, and the discussion will be upon *Lantern Matters*. Visitors are invited.

Correspondence.

227 Correspondents should never write on both sides of the paper.

FIFTY SITTINGS FOR A PORTRAIT.

To the Editors.

GENTLEMEN,—Mr. R. Barrett's reply to the question at issue, I think, cannot be taken as successful and satisfactory. In his former article he introduced the names of celebrated artists and told us how many sittings they wanted to produce a portrait, and that nowadays by the aid of photography we have done with such troubles. Now to what comes the help Mr. R. Barrett advises us to obtain from photography? He says, in the first instance, the "independent" artist shall take into account a photograph which the people, ordering a large portrait, and all their friends, regard as a successful one. I venture to say, when the "independent" artist would allow at all such interference and try this way to execute his work, it would greatly embarrass him and surely not lessen his labour in any direction, including the sittings, as every artist of experience will testify, provided his aim being a work of art. Mr. R. Barrett himself testifies this indirectly, perhaps unconsciously, by his remark: "Of course there are many artists like 'A Painter' who will not accept the assistance of photography, such as Sir F. Leighton or Sir J. E. Millais." Then he goes on to say: "But there are also many exceedingly good men, upon whom fortune has not smiled so kindly, who are obliged to humble their pride and accept photography willingly as a

help." What can this suggestion mean? Does it mean that these exceedingly good men have not had the opportunity to learn the necessary technical adroitness of drawing sufficiently and therefore must look out for help? In such case they cannot come in consideration here at all, because it must be expected of any one who claims to be classed as a portrait painter, that he is possessed of sufficient preliminary knowledge, skill, and practical experience, to execute his work. In possession of such qualities it will be of no consequence, indeed, to have resource to any such help as Mr. R. Barrett recommends. Besides this, the principle of art, as sanctioned by all the art academies everywhere, has been, and is still, that any work not based entirely upon the study of nature cannot come in the category of art. Therefore is it not pride or caprice, as Mr. R. Barrett seems to fancy, which compels Sir F. Leighton and all the rest to have nature only for a guide, but it is because this grants the only means to come to any satisfactory result, and thus your correspondent "An Artist" speaks out rightly in a few words all that can be said about the whole matter, namely, "No true artist would condescend to use photography as a help, and if he did it would only lead him astray." The other remarks in Mr. R. Barrett's answer I consider as irrelevant, and do not care to reply to, and I think we have had now enough said about the question on both sides, so as to enable any impartial reader who cares for it to draw his own conclusion, and I therefore propose to drop the matter.

Thanking for your kindness to lend space for my notes in your valuable JOURNAL,—I am, yours, &c.,
A PAINTER.
Liverpool, August 22, 1887.

To the Editors.

GENTLEMEN,—Mr. Redmond Barrett need not have excepted Sir Frederick Leighton from those artists who accept the assistance of photography. Sir Frederick told me himself that the portrait he painted two years ago of a daughter of Lord Rosebery was done chiefly from photographs, as there was a difficulty about getting sittings. Your anonymous correspondent signing himself "An Artist" asserts that "no true artist would condescend to use photography as a help, and if he did it would only lead him astray." Hence, gentlemen, we learn not only that "photography is photography, but art is art," but also that Sir Frederick Leighton cannot be an artist!—I am, yours, &c.,
1, Cheniston Studios, Kensington, W.
August 20, 1887.

HERBERT S. MOBERLY.

To the Editors.

GENTLEMEN,—Just a few words on the question between artists and photographers. A year or two ago there was a short anecdote in one of the comic papers that seems much to the point. A lady had a portrait painted, and when it came home complained that it was not a bit like. Said the painter, "If you wanted a likeness, madam, you should have gone to one of those photograph fellows. I am thankful to say that I am an artist." (I quote from memory.) And *apropos* of nothing in particular, I have somewhere seen a signboard which read, "Plumber, Artist, and Glazier." Can this be the artist who so anxiously disavows ever receiving aid from photography?

Yet I think that photographers have brought on themselves many of the impertinences from the minor artists of which they complain. Many of us were rather astonished that the judges in a recent exhibition seemed to be selected for their ignorance of photography, and certainly one at least of their decisions excited universal wonder. The artists (I mean painters) never did such a foolish thing as to leave the judging of their works to photographers. If they did, I fancy some even of the R.A.'s. would be placed in a back seat. I confess I do not like all this fawning on artists for a little praise and encouragement. We deserve what we get—more kicks than halfpence. Why can't we go our own way and stand on our own legs?—I am, yours, &c.,

PHOTOGRAPHER (Not Photographic Artist).

To the Editors.

GENTLEMEN,—I hope you will forgive me for writing a few lines in answer to "A Painter," although he addresses you (not me) in his letter which appeared in the last issue of your JOURNAL. I am responsible for his displeasure, and now I am no longer "laid up" I do not wish to appear to shirk the duty of giving him every satisfaction.

In the first place, I would recommend him before going any further into this matter to read over carefully the original "par" which has led to this little storm. I think by so doing he will find that he has somewhat got "the wrong end of the stick." I do not think I ever suggested making artists by the aid of photography, especially of such calibre as those for whose memory he is so particular. I feel sure no man has a greater respect for their works than I have. Nevertheless, I still hold that photography could have been a help to them if they would have condescended to use it. A stick or a crutch is no use or help to a lame man if he won't use either, and to such as won't use it photography is similarly placed.

"A Painter," again, mentions that all paintings which have received help from photography as being only imitations. That point I consider answered by my last letter.

In your correspondent's last letter (forgive me if I am wrong) I seem to

think that the question is suggested, "Will photography help to produce such artistic work as that left to us by Sir Joshua Reynolds and Sir Thomas Lawrence?" I must say I think this a very foolish way of putting it, and one that can serve no practical good. The best way of answering it that occurs to me is by asking, "How many artists have we to-day who—with or without the aid of photography—can produce such works?"

If my last letter will not prove sufficient to convince "A Painter" that there are many good artists who accept photography as a help, I will have much pleasure in giving further examples. I also hope that he realises the fact that works of art—*real art*—can be produced without showing the strokes of the brush. I can also satisfy him on this point further, if he desire it. I presume he knows that sculptors (I hope I may term them also artists) in very many cases receive help from photography.

To your correspondent who signs himself "An Artist" these lines should be an answer, as he only seems to say "Ditto" to "A Painter." He says "art is art;" he seems to possess enough of it not to offer a very strong opinion. If he would like to ask any special question I will be happy to give the best answer I can. I can say no more.

I beg to thank "One who finds Photography a Help" for his kind offer to take my part. Had I not been unwell and missed reading my JOURNAL I certainly would not have let "A Painter" think I was unable to answer his easy question.—I am, yours, &c.,
REDMOND BARRETT.

THE FLORENCE EXHIBITION.

To the Editors.

GENTLEMEN,—The translator was correct in presuming that the exhibitor of the frame of transparencies at the Florence Photographic Exhibition was Mr. A. Cowan—or rather they were transparencies produced by Mr. Cowan on his chloride plates and exhibited by us.—We are, yours, &c.,
MARION & Co.

22 and 23, Soho-square, London, W., August 23, 1887.

PHOTOGRAPHIC ENGRAVING.

To the Editors.

GENTLEMEN,—Mr. Stebbing, in your issue of August 12, 1887, describes a process of photographic engraving, the invention of M. Sartirana, which was brought before the notice of the last monthly meeting of the Photographic Society of France. I beg to call attention to the fact that I patented the method twenty-one years ago, namely, May 9, 1866. The following is copied from my specification:—

"Raised surfaces prepared as above described (see patent) may be used advantageously to produce engraved plates, by machine copying or ruling with the instrument known as the pantagraph, the irregularities of the surface which is being copied producing undulations in the lines whilst the instrument rules on the copper or other plate, as is well understood."

I tried to get the patent taken up by the Woodbury Company, which was then working at Brompton, but I met with no encouragement.

In the patent will be found the germ of Woodbury's latest process—Stannotype. My use of the tinfoil on a gelatine relief was, however, for another purpose; but as applied to the gelatine relief, could be used for Stannotype printing.

In this country, unfortunately for inventors, "the voice of one crying in the wilderness" has to be pitched very high indeed before you get attention. The patent never brought me in a penny.

I shall feel obliged by your calling Mr. Stebbing's attention to the facts I have given above.—I am, yours, &c.,
D. C. DALLAS.
9, Farnival-street, London, August 23, 1887.

A QUESTION OF COPYRIGHT.

To the Editors.

GENTLEMEN,—What is the law of copyright in the following case?

A statue of the Queen has been erected in this city, and was unveiled last week. A local photographer is advertising that he has the sole right of photographing this statue, and cautions other artists from infringing what he calls his sole right of reproducing the same.

Can any copyright exist in a public statue any more than in a public building—to wit, the Houses of Parliament, Albert Memorial, or the elaborate monumental structure where once stood Temple Bar?—I am, yours, &c.,
A HAMPSHIRE PHOTOGRAPHER.

Winchester, August 23, 1887.

THE PORTRAIT NEGATIVE.

To the Editors.

GENTLEMEN,—Feathers are said to show how the wind blows, and the correspondence which has appeared in your excellent JOURNAL may be taken as indicating the direction of the wind with regard to the portrait negative. Allow me, however, to congratulate your correspondents, and all interested in the negative, on the resurrection of a venerable friend from the dead—if one can be said to be dead who has never departed out of life.

The law is brief and plain, as shown in the extracts from Mr. Foster's articles in the letter from "J. F." It gives to the photographer his much-prized negative and it also gives to the sitter his much-valued protection.

Evidently your correspondents have been ignorant of the existence of this law, and this being so it is not to be wondered at that sitters, also, are ignorant of it, and that consequently no registration by them of their copyright takes place.

With professional photographers I find no fault. I have no need to do so. I believe that they are an honourable body of men, in whom their clients may have the fullest confidence. Yet among photographers, as among other honourable professions, there are to be found unscrupulous persons without knowledge of moral right, with only selfish instincts, and these very strong, who would for gain rob the hands that gave them bread. These persons are not a new importation into the profession. Mr. Foster advised caution when dealing with them.

The law, on the resurrection of which I have offered congratulations, deals with these persons and clearly settles the pound of flesh, and, should it become generally known, clients will in many cases alter use and wont. I may add that the law of Copyright may be had post-free for fourpence from Eyre & Spottiswoode, East Harding-street, E.C. It is dated 1862.—I am, yours, &c.,
MILLIE.

August 19, 1887.

BLUE COPYING INK ON PHOTOGRAPHS.

To the Editors.

GENTLEMEN,—Having occasionally a large number of photographs to mount—taken in all quarters of the globe—I am often very much surprised that publishers, and sometimes even photographers, have recourse to a rubber stamp and copying ink in order to advertise themselves; foreigners are, as a rule, the greatest sinners in this respect, though a few English photographers sin grievously. Fancy having a hundred or so 12 × 10 photographs to mount, each one having copying ink on the back; they must be wetted and placed on the slab of glass or piece of paper singly in order to apply the mountant, for if you attempt to place another print on top of "Tom Jones, publisher"—hey, presto! the transfer is complete even to the punctuation. "Tom Jones" on an Italian sky is unique—almost equal to the balloon system of advertising soap.

My object in writing this to the JOURNAL is to ask all photographers who use copying ink to refrain from doing so; it will not certainly add to the permanence of the print. Placing paper between the prints disposes of the difficulty to some extent, but why not write or print your name and address on the negative?—it will appear then, whether the print be mounted or unmounted; or simply use a steel dye minus ink. Please do so, and less big D's will be uttered by the useful people we call mounters.—I am, yours, &c.,
MOUNTER.

Exchange Column.

* * No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Will exchange new seven-string silver-plated hanjo for presses, backgrounds, or accessories.—Address, CURTIS, Sutton, Surrey.

Wanted, camera and lens by good maker in exchange for tricycle with ball bearings, luggage carrier, and lamp.—Address, S. NICHOLS, Railway-road, Ormskirk.

Will exchange Dallmeyer's 3d patent portrait lens for 2d patent portrait lens of same maker.—Address, L. GRIMSHAW, Dale-street, Haslingden, near Manchester.

Will give quarter-plate camera, lens, and stand, with six Tyler's double slides, for Gem or Victoria camera and lenses.—Address, W. R. FAIRY, Harrold, Bedfordshire.

Wanted, stereoscopic camera in exchange for half-plate instantaneous lens, adjustable diaphragms, and patent shutter (Lancaster's).—Address, LINDSAY, Pine-grove, Selkirk.

Answers to Correspondents.

K. W. (South Shields).—We must decline giving any opinion concerning paper of which we know nothing.

D. S.—The most that we can do in the case mentioned is to receive the letter and forward it to the required destination.

JUBAR.—As you describe the lens we cannot understand its construction. It will only cost you a few pence to send it to us for examination.

ALEX. TAYLOR.—Get a doublet lens of wide angle, such as one which with a focus of four and a half or five inches will cover a whole-plate, or in these proportions.

R. C. SAWYER.—If the albumen behaves as you describe it is clear that you have not "whipped" it sufficiently to produce limpidity. It should be beaten up until the vessel containing it can be inverted without any running out.

SAVE ALL.—It is no use saving the developing solution from dry plates, because it contains no silver. Indeed, if you add this to the residues containing chloride it may do harm, inasmuch as the ammonia might dissolve some of it, hence it would go down the sink when the residue was decanted.

W.—Several different methods of producing type blocks have from time to time been given in this JOURNAL, but none of them have been all that could be desired. Type blocks in half tone are, however, produced which, with the aid of the engraver to touch them up, and with careful printing, yield excellent results, but those who make them preserve the details of the processes they employ as trade secrets.

F. A. writes to ask us the discount a certain maker of dry plates allows off his list price.—We cannot answer the question. Why does not our correspondent write to the maker direct for the information?

LOLO inquires: "Can you tell me if using gallic acid in mistake for pyrogallie acid would have the effect of frilling a gelatine negative so badly that the entire film slipped off, leaving the glass clean?"—In reply: We should not expect it to have any such effect. The frilling must have been brought about by some other cause.

T. HILLIER.—Although you have used the lime toning bath, "which is said to give black tones," you clearly have not obtained them, nor will you from such negatives as you are using. Weak and feeble negatives will never yield prints with rich black tones whatever bath may be employed. The fault lies not with the bath but with the negatives.

S. RAY asks if a paraffine cask will do for collecting the silver residues. He says that, although he has washed several times with soda and water, and has kept water standing in it for more than a week, he cannot get rid of the smell of the oil.—The cask will do quite well for the purpose, and the smell of the paraffine will do no harm whatever.

S. J. J. wishes to know if prints on bromide paper cannot be developed with alkaline pyro instead of ferrous oxalate.—Prints on bromide paper can be developed with pyrogallie acid, but ferrous oxalate is preferred, on account of the better tones it yields. Moreover, the pyro has a tendency to stain the paper, hence such pure whites are not obtained with it as with the iron developer.

R. JOHNSON asks if it be necessary in making enlarged negatives that the transparency be by the carbon process, as he has been told it must.—It is not at all necessary that the transparency be a carbon one, as one by any other process will answer quite as well. All that is required is a good transparency for the purpose, and this can be made by any process. Ordinary dry plates are very generally employed now.

ALPHA.—1. We cannot give you any idea of the exposure required as you do not say the rapidity of the plates you are using. "Four times wet collodion" means nothing unless you define the sensitiveness of the wet collodion with which you compare your plates.—2. We have not tried the first shutter you name, and we know of no objection to the second.—3. Increasing the proportion of pyrogallie acid conduces to density.

W. C. says he has just made up a silver bath for paper, as he wishes to try his hand at sensitising his own, and complains that when the silver was added to the distilled water, which he obtained from a local chemist, it became "milky," and after standing for a time a white deposit settled at the bottom of the vessel. He asks if this is the general behaviour of the bath.—No, it is not. The fault lies with the water, which evidently contains some impurity, probably a chloride. If the water had been pure the solution would have been clear. If the bath be filtered it will probably work all right.

MR. G. P. CARTLAND, of Windsor, has been appointed Photographer to the Queen by warrant from the Lord Chamberlain.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, August 31, 1887, will be on *Stripping Films*. Saturday outing at Kew. Meet at bridge foot at six o'clock.

NORTH LONDON PHOTOGRAPHIC SOCIETY.—Excursions, on August 27 to Oakleigh Park, train from Broad-street at forty-seven minutes past two p.m.; and on September 3 to Mill Hill, trains from Broad-street at twenty-seven minutes past two p.m., and from Moorgate-street at thirty-eight minutes past two p.m.

MR. B. J. SAYCE sends us a *Note-book for Photographic Exposures* made in connexion with roll holders. Those in common use hitherto do not, in Mr. Sayce's opinion, quite meet the wants of those who employ films, which has led to his having devised the one a copy of which is before us, and which, Mr. Sayce says, any publisher is at liberty to reproduce. It certainly forms a most complete note-book for the purpose intended.

PHOTOGRAPHIC SOCIETY OF INDIA.—First Annual Exhibition, 1888. 1. The Exhibition will be opened early in January for a period of about three weeks. 2. Medals will be awarded by judges to be appointed by the Society. 3. Photographs need not be framed, but they must be mounted, and in the hands of the Secretaries before January 1. 4. Carriage on exhibits must be prepaid and full instructions given as to return or sale. 5. Photographs to which medals are awarded will become the property of the Society, and the Society reserves the right of ordering further copies to be printed for distribution among members before a medal is despatched. The extra copies ordered will be paid for at fair rates. 6. The following medals will be open for competition:—Class 1 (open to the world), His Excellency the Viceroy of India's own special medal and the Society's gold medal for the best photograph in the Exhibition; a silver medal will be held at the disposal of the judges. Class 2 (open to the amateurs of India), silver medal for best photograph in the Exhibition; silver medal for best set of not less than four photographs; a silver medal to be at the disposal of the judges. 7. All exhibits to be forwarded to the Secretaries, Photographic Society of India, 8, Clive-street, Calcutta.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1426. Vol. XXXIV.—SEPTEMBER 2, 1887.

THE EFFECT OF QUANTITY OF SOLUTION ON DEVELOPMENT.

RESUMING this subject where we left it last week we may now turn to the more purely practical side of the question, and consider how the matter of bulk of developing solution actually affects the character of the result. As may be gathered from what has already been said, we hold that, though the composition of the wet and dry plate developers is totally different and the manner in which the image is formed in the two cases equally distinct, yet in a general way the effect produced by increasing or diminishing the quantity of solution is similar in both cases. In the former, by limiting the quantity of developer, the silver which goes by deposition to form the image is concentrated and so leads to contrast, while in the latter the bromine liberated in the formation of the picture is in like manner utilised with a similar result.

In speaking of the wet plate developer we must be understood to refer to the processes of "silver development" generally, that is to say, those processes in which a soluble silver salt—usually the nitrate—is deposited by means of a reducing agent upon the exposed portions of the film. This method is equally applicable to dry plates, and before the introduction of the alkaline form was universally employed for the purpose. But this difference exists when operating upon dried films, from which all traces of free silver have been carefully removed; the silver is added directly to the reducing solution, whether gallic acid, pyro, or ferrous sulphate, instead of, as in the case of a wet plate, being derived from the excess of bath solution clinging to its surface.

Now it will be remembered that, in conducting this style of development of dry plates, and equally in redeveloping or intensifying films of any description in cases of under exposure or when the object is to subdue or hold in check violent contrasts, it is the practice to add the silver slowly and in very small quantity, which virtually amounts to using a large proportion of the reducing agent. On the other hand, where over exposure is the condition, or contrast is desirable, the silver is used more liberally, and the circumstances then more nearly resemble the application to the plate of a small quantity of developer.

We should, therefore, be guided by precisely similar ideas in the treatment of modern dry plates. It has been remarked in our former article that the difference in the results obtained by varying the quantity of developing solution may not be great, but there may be circumstances under which the very slightest variation should be seized as having importance, notably in extremely short exposures. The problem has long

been, as Colonel Wortley happily phrased it, "how to get most out of a plate." The Colonel's plan was to give the plate a preliminary soaking in dilute alkali previous to the application of the pyro, a method which may be considered to have for its *rationale* the conversion of the bromine dissociated by the action of light into less harmful alkaline bromide. The first attack of the developer is then made under conditions more favourable to the production of the best results, for not only is its alkalinity—and therefore its energy—not reduced by combination with the dissociated bromine, but, what is perhaps of higher moment, the *reversing* action of the latter is absent. All who have tried Colonel Wortley's plan know not only how it answers the intended purpose, but also how much more rapidly development takes place, especially in the early stage.

If so apparently small a matter as this exercise such beneficial results—results not otherwise obtainable by increasing the strength of the developer or "forcing," which only end in fogging the plate—it behoves us to avail ourselves of every means, however slight, tending in the same direction. This we can do by increasing the quantity of the developer, and in adopting that course we introduce not the faintest element of danger to counterbalance the anticipated benefit. If we resort to the preliminary soaking in ammonia, followed by washing, and then apply double or treble the usual quantity of developer, we may consider that we have done all it is possible to do in the way of making the most of an extremely brief exposure; and it is only under such circumstances that it becomes necessary to trouble with the niceties of manipulation.

Some of our readers may perhaps imagine that the same result can be arrived at by adhering to the normal quantity of solution and using a proportionately less quantity of restraining bromide, but such is far from being the case. At the precise moment of applying the developer to the plate, and at that moment only, similar conditions prevail; but instantly the smaller volume of solution commences to change its condition "by leaps and bounds," as compared with the greater bulk. Its active alkali is not only neutralised, but converted into equally active restrainer, and this in inverse ratio to its volume, so that in a very short time the solution which, if it had remained at its normal developing strength would have sufficed to bring out an image full of detail, is reduced to such a condition as to produce only a hard, under-exposed result.

It has been stated by Burton and others that the effect of

excess of bromide in the developer is merely to retard its action, and that if a sufficient time be allowed the final results will be identical with equal exposures, no matter how much bromide is employed. This is true to a certain extent only, namely, where an adequate, or we may say, a "full" exposure has been given. But when the exposure is curtailed to the utmost, it becomes important to work with as little restraining bromide as possible. It cannot be altogether dispensed with, especially when, as in instantaneous work, the development must be, in a measure, forced, certainly prolonged, but the quantity used should be reduced to a minimum. With such subjects or exposures, too, the character of the image is formed at the earliest stage of development, and any error then is irremediable at a later stage. The late Major Russell pointed out years ago the importance of using bromide sparingly in the first stage of development, showing that a proportion which might be added with perfect impunity later on in the process would inevitably ruin the negative if employed at first.

The necessity, then, for commencing the development of a delicate subject with a solution which, while sufficiently restrained in the first instance to ward off fog in the later stages, will retain its original character with but comparatively little change, will be recognised by all who care to give the subject a moment's thought. And it will further be evident that the greater the volume of solution the greater its stability or freedom from tendency to alter during the process of development.

An absolutely perfect method of developing brief exposures will perhaps not be available until we can imbue the sensitive film with some substance which, while free from restraining or other injurious action, shall possess a stronger affinity for bromine than the silver compound forming the invisible image. In this manner we should render inert the dissociated bromine and prevent its reversing action: the preliminary soaking of the film in alkali only partially effects this by converting the free bromine into a restrainer devoid of reversing power, but it cannot prevent a partial recombination, the instant the film is wetted, between the bromine and the silver from which it has been loosened by light.

It is not only with instantaneous exposures that the increase of volume of the developing solution will prove useful, but in any case where it is desirable to subdue unnatural contrasts, as, for instance, in photographing dark interiors, woodland scenes, or any subjects where masses of heavy foliage, or rocks in deep shadow, have to be developed on the same plate as the unclouded sky. In such cases the employment of a large volume of solution, by diluting the restraining power of the liberated bromine, places less check upon the development of the feebler details, and these are consequently brought to printing value before the high lights have acquired too great density.

For cloud negatives, for copying black and white, and for all subjects where contrast is wanted, the opposite course should be pursued and the volume of solution kept as low as possible. But here it is obviously possible to produce the same or a greater result by the direct addition of bromide to the developer, if necessary; so that it is scarcely worth while to risk other troubles by unnecessarily cutting down the quantity.

To those engaged in the production of positives on gelatinobromide paper, especially where a number of prints are developed in the same solution, the importance, in securing uniformity of result, of employing a considerable volume of developer, no matter whether it be ferrous oxalate or pyro, must be palpable. To expect any two successive prints to develop alike in a quantity of solution only sufficient for one

is to anticipate an impossibility; whereas, if the quantity necessary for a dozen or half a dozen be mixed at once and used for its proper number, the development of the whole would prove tolerably uniform.

A PRIZE of a thousand francs, or, in round numbers, forty pounds, is offered by M. Davanne for a process by which a plate combining the advantages of both gelatine and collodion may be manufactured, the chief conditions being great simplicity in the operations combined with extreme sensitiveness. Descriptions of the process sent in for competition should be very full, be accompanied by negatives and prints, and sent in before the thirty-first of December next.

RECENTLY we had an excellent opportunity of putting again to the test of practice the method we described a short time ago for combating violent frilling tendencies in a gelatine plate. We made two exposures of a certain subject upon plates which had been in our possession for a considerable length of time, but of whose properties we believed we had a complete recollection. To our surprise, however, the first plate we developed became covered with blisters directly after we put it to wash when removed from the hypo, and we were just in time to prevent a similar disaster with the second plate. We placed it, without fixing and after well washing the developer away, in a drying cupboard till it was quite hard again, and then put it to fix. The result was entire absence of any tendency whatever to either frill or blister.

M. JANSSEN brought before the Paris Academy of Sciences on the 16th ult. an account of the work carried on at the Meudon Observatory, with the object of perfecting solar photography and the study of the laws governing the absorption of luminous rays by the gas of the atmosphere. The photographing of the sun has made great progress, pictures being now obtained containing details from the centre to the edge of the disc, and embracing even details in the penumbra of spots. At first difficulties were presented by the immense difference of luminosity in various portions of the solar surface. M. Janssen presented proofs of negatives of a large sunspot which was visible about the middle of July last, and in it the striæ of the penumbra were seen to resolve themselves into granulations, a circumstance which enabled him to draw the conclusion that the solar surface is completely uniform.

Our always interesting contemporary *La Nature* has recently been giving its readers popular articles on various aspects of photography, the last, under the heading of *Photography and Forgery*, being an illustrated description of the various modes in which forged cheques and bank-notes, and even counterfeit coins, have been detected by the agency of the camera. Of course the principle of these processes has long been familiar to our readers, but the illustrations deserve passing notice. M. Gobert, a clever expert of the Bank of France, was able to prove conclusively before a legal tribunal the fact of an erasure and forgery in a cheque which they would have honoured, but for their suspicions having been aroused by non-receipt of advice note, and a reproduction of the particular cheque is given in *La Nature*, the printing block having been produced by photographic agency alone. An enlargement on a large scale showed conclusively the original writing had been washed away, the grain and the appearance of the paper being completely modified by the action of the chemical employed. So that the forgery should not be detected by any difference in the colour of the ink, the whole sum had been taken out and the new written in its place; but the photograph plainly showed the new figures under the old. As the writer properly points out, a similar proof might have been obtained by chemical means, but in that case the forgery would be obliterated, while in the photograph both are shown, one superimposed upon another. A similar treatment of a genuine and a counterfeit coin is also shown, but the difference is so slight as to require careful scrutiny before it can be discerned.

ANOTHER popular article consists in a description of a very old photographic trick—the photographing upon one plate the same person several times repeated in various positions. Thus we have

an artist painting, as it were, at his own portrait, while an onlooker is perceived to be a third representation of the same head. Again, we have a two-faced head surmounted by a single hat and joined to the body, also two-fronted, by an impossible and absurd neck. We need scarcely describe to our readers the method of working this very old trick, but the periodical named contains full details, and is illustrated with a drawing of the dark slide with the double sliding back. We think it is about a quarter of a century since these useless but amusing photographic toys were first invented.

PHOTOGRAPHERS are, or have been, great experimenters with varnishes, and they will, no doubt, be interested in the announcement of a new varnish possessing very remarkable properties. It has been devised for aeronautic use, but from the published description it would appear to be available for photographers also. It is the invention of M. Jovis, the Director of the Aeronautic Union of France, which has applied to the Société d'Encouragement for help to give this new industrial branch a worthy development. The varnish is stated to possess an enviable record of good qualities; in fact, the very excellent reputation given to it excites doubt. It is of great flexibility, though possessing no oleaginous base, and which, adding little to weight, confers great impermeability; it is suitable for paintings, wainscoting, &c., and will not grow mouldy; it can be exposed to great fluctuations of temperature without alteration; and, finally, the by-products of its manufacture can be utilised entirely for a variety of useful purposes. So far as we can learn, the mode of manufacture has not been divulged; but it is evident that if the above description of its properties at all tallies with actual facts, it ought to be of prime use in photographic operations.

THERE are a large number of temperature regulators—instruments for keeping water baths, cupboards, &c., at a constant temperature, but almost all are designed for use with gas as the heating agent. It is evident there must be a large number of experiments at work where gas is not available, and to them these regulators are useless. Mr. W. C. Borden, M.D., describes in the *American Monthly Microscopical Journal* a neat arrangement devised for histological purposes, but alike useful to the photographer, in which any ordinary oil or alcoholic heating agent may be used, the check action being supplied by a small electric battery. The principle of action is a mercury cup immersed in the bath, which forms an electric connection when the desired heat is exceeded, the result being a deflection of the heated air until the temperature is reduced to the required extent, being brought about by a small electro-magnet actuated at the required moment by the current brought into play by the little phial of mercury. The method seems both practical and useful.

A VISIT TO THE ORDNANCE SURVEY OFFICE, SOUTHAMPTON.

(By our Special Correspondent.)

IN giving a brief description of the work carried on at the Ordnance Survey Office, Southampton, it may be well, at the outset, to give some general information as to what is done there, and then to explain how it is accomplished. The Southampton establishment is probably the most complete of its kind in the world; the various buildings and grounds occupy a space of something like seven acres, and it gives employment to between eight and nine hundred persons. Of these about eighty are military—the Royal Engineers—the remainder being civilians. The entire establishment is under the command of Col. Sir S. W. Wilson, K.O.B., R.E., the Director-General, the different departments being under the immediate direction of other officers of the Royal Engineers, Col. Bolland, Col. White, Capt. Sankey, and others, the photographic department being under the charge of Sergeant-Major Algar, R.E. It may here be mentioned that the greater portion of the work carried out in this department is done by the military, and one cannot fail but to be impressed with the interest and pride they appear to take in their work.

The Ordnance maps, as published, are on several different scales. For example, there is a general map of Great Britain and Ireland to the scale of one inch to the mile; there are county maps six inches to

the mile; there are parish maps on the scale of $\frac{1}{25000}$, or a little over twenty-five inches to the mile; and town maps on a scale of $\frac{1}{12500}$, or a trifle over ten feet to the mile. In addition to these, which may be termed the standard scales, there are various miscellaneous maps issued. For instance, there are indexes showing the positions of the different sheets. These, also, are on different scales, such as ten miles to the inch, fifty miles to the inch, and some are forty, and some thirty. A large proportion of the maps, in addition to being published in line, are also issued with the hills shaded, others showing the contours in outline only. The work of the Survey Office is not confined to the production of maps alone, as it has issued many other publications, such as *Surveys, Photographs, and Models of Jerusalem and Mount Sinai; a Facsimile of Doomsday Book; Black-letter Prayer Book of 1636; National Manuscripts of England, Scotland, and Ireland; Anglo-Saxon Charters, &c.* Until quite recently the office had a depot in London for the sale of the maps and the other productions, but this is now abolished, and the sole agency is at present in the hands of Mr. E. Stanford, of Charing Cross, from whom any of the maps or other publications can be obtained for a trifling sum.

Although the maps are issued on so many different scales they are all obtained from single original drawings. Towns of more than 4000 inhabitants are drawn to a scale of $\frac{1}{2500}$, commonly called the ten-foot scale. On this scale every inch represents a little over forty-one feet. Country districts are drawn to the scale of $\frac{1}{5000}$, usually termed the twenty-five-inch scale. On this scale each square inch on the map represents approximately one acre. The drawings are all made on sheets of stout paper measuring thirty-eight inches by twenty-five, and from these all the smaller scales are produced by photography and printed by zincography. On the walls of the library of the Institution are shown some gigantic maps to the various scales, built up of the sections as issued to the public, and so neatly and accurately are they joined that the junctures are quite imperceptible. The methods and appliances by which the work is accomplished will now be briefly described; first, the photographic department.

The camera in which the largest negatives are taken is a substantial building standing by itself in the grounds; in this the operators work. In one end of the building is fitted a lens, six inches or so in diameter, specially constructed for the establishment by Messrs. Ross & Co. Opposite this, on the outside, is a massive iron easel, which carries a large board, upon which the maps to be copied are fixed. The easel travels on iron rails, upon which it runs freely, and is provided with a fixing arrangement by which the utmost rigidity is secured after it is once placed in position. It is also furnished with screw adjustments, by means of which the object to be copied can be moved vertically or horizontally with the greatest nicety, without altering its parallelism. In the room, behind the lens, is fixed a firm table, on which are two A-shaped bars or rails, upon which travels a strongly-made frame, like the back of an ordinary camera. This frame carries the ground-glass focussing screen, and is actuated by a quick acting screw for adjusting the focus. After the focus has been obtained the screen is removed and replaced by an open frame, somewhat resembling the carrier of an ordinary dark slide; in this the plate is secured during exposure. The plates are sensitised in a horizontal bath. This is a large wooden tray lined with gutta-percha; the latter, in order to prevent its acting injuriously on the silver solution, being well coated with shellac varnish. It was mentioned that, although many other plans of making large bath vessels "silver solution proof" had been tried, none had proved so efficient as this. Here, in this camera are, of course, sinks and the usual dark room appliances. This camera is chiefly devoted to the production of the largest size negatives, and it is scarcely necessary to say that they must be, as they are, in every respect, of the most perfect description; and so excellently does the lens do its work that no difference in definition can be detected between the centre and the extreme corners of the plate. These negatives are all on plate glass, and measure somewhere about four feet by three. I may add that I was shown a large number of them, and I must say they are technically the most perfect negatives I have ever yet seen of these dimensions.

The smaller negatives are taken in the studios, of which there are two, both raised twelve feet or so from the ground. Ascending

a staircase, one enters the smaller, or old, studio, which is a handsome glass structure, well adapted to photographic purposes. Leaving this by a gallery we enter the new studio, where the greater portion of the smaller work is now done. This building, which has only been erected during the last year, is most complete in every way. It measures about forty-five feet by twenty-five, is lofty and is well ventilated. It is built on massive arches, and has an asphalted or concrete floor. So rigid is the floor, that the operators walk about during exposures without the slightest fear of causing vibration. In the floor are let in two pairs of iron rails, upon which the camera stands travel. There are two huge cameras in use here—one is fitted with a Ross lens, the counterpart of the one previously referred to, and the other with one of the rectilinear type by Dallmeyer.

One of the camera stands is of wood and the other of iron. This latter requires description. It has been constructed to the design of Sergeant-Major Algar, who, as before-mentioned, has the charge of this department, and it is one of the most perfect for its purpose yet made. Although it is most massive it can be moved backwards or forwards on its rails with the slightest pressure, and, when it is got into position a very ingenious though simple contrivance, by the action of a lever, enables the wheels upon which it travels to be put out of gear, so that the stand then rests as a dead weight upon the floor itself. As the stand weighs over half a ton, some idea may be formed of its rigidity. It has the usual adjustments of a camera stand, with the addition of one which enables the camera to be moved laterally without disturbing the parallelism. The cameras are of the usual type of copying camera, and are provided with a series of elongating cones, all of which are interchangeable. At the end of the studio, at right angles to the rails, are the copying easels. These are of iron, and furnished with screw adjustments, which enables the copying board to be moved either horizontally or vertically as may be required. The copying boards are large enough to take four of the largest size maps at a time. The sheets are secured to the boards by pins, and so neatly is this done that the junctures scarcely show at all in the negative, and, where they do, only in such a manner that they can easily be touched out. Behind the studio are the dark rooms, about which little need be said, except that for size or convenience they are in keeping with the other portions of the establishment.

One of the essential qualities of a negative for photo-zincography or photo-lithography is that the lines should be represented by clear glass while the other portions are perfectly opaque. Only those who have tried to produce negatives with these qualities know the difficulty there is in obtaining them without, at the same time, clogging up the finer details. At Southampton this is accomplished most perfectly. It may be mentioned that only the wet collodion process is employed. Here are the details: The collodion used is Rouch's (Hardwich's formula), simply iodised with potassium iodide. In winter a small proportion of bromide is sometimes added, but not as a rule. The plates are all sensitised in horizontal baths, the silver solution being of the usual strength and made slightly acid. The negatives are developed with the ordinary iron developer, and fixed in a solution of cyanide of potassium. With the exception of the use of a simply iodised collodion there is no departure from the everyday method of working wet collodion. After fixing, however, the negatives require intensification; this is done by immersing them first in a solution of bromide of copper until the image is whitened and then, after thorough washing, treating them with a solution of nitrate of silver. This treatment confers upon them great density without in any way clogging up the finest lines. Of all the methods of intensifying which have been published, none answer the requirements of the Southampton establishment so well as this. All the negatives, both large and small, are varnished with dammar varnish applied cold, hence the risk of cracking the thicker plates by heating, which would have to be done were a spirit varnish employed, is avoided. This varnish is also found the best for working upon, as it does not chip up under the etching point, which in some cases has to be used freely. The varnish is made by simply dissolving the best dammar resin in pure benzole.

It goes without saying that in copying maps, the national ones in particular, extreme accuracy to scale is of the utmost importance—an error of the sixteenth of an inch in a couple of feet would, of

course, be fatal in the finished result. As the image has to be obtained from the negative in fatty ink on paper, and it has to be transferred to the zinc while it is damp, it follows, as paper expands when it is wetted, that if the negative were made the size of the finished map it would prove too large, hence allowance has to be made for this in the copying. After every negative has been examined and passed, a print is taken from it by the platinum process. This then goes into another department, together with the original from which the negative was made, for examination, when any defects that need remedying, or alteration that may be required, are marked upon the print, to be afterwards dealt with by working upon the negative. So far as photographic defects are concerned there is never much to remedy, but sometimes considerable alterations have to be made or fresh details introduced.

(To be continued.)

ECHOES FROM THE SOCIETIES.

THE French Photographic Society must surely be at a loss for matter with which to fill up their meetings if we may judge from some of the recent reports. For instance, we are told that the Secretary announced, apparently as something worth announcing, that "a Belgian" had published as a practicable method of preventing unmounted prints curling their immersion in a mixture of alcohol, glycerine, and water. It really seems a pity to waste the alcohol and glycerine, for the water alone would answer quite as well if they were left in it until required for mounting, or they might be preserved between damp blotting-paper in waterproof portfolios, and in either case would remain as permanent as under the glycerine treatment, I should think.

Then "a great discussion" took place as to whether the practice of focussing with a large diaphragm, and substituting a smaller one when the picture is taken, is a feasible and advisable one, and it was resolved to solicit a theoretical paper on the subject. I am afraid the paper when it appears will not bring much balm to the souls of French amateurs who wish to continue the convenient practice, for cheap single lenses are mainly employed on that side of *La Manche*, and aplanatic lenses are regarded as almost unnecessary luxuries in landscape work. There must be a few aplanatic lenses in use among the members, however, since we are told "a great divergency of opinion was manifested on the subject." If the parties to the discussion each spoke from his own practical experience, no doubt the suggested theoretical paper may bring general conviction.

Next "the cabinet makers present" exhibited "some acrimony"—an euphemism, I presume, for "began quarrelling"—over the right to call a camera "*Le Polygraph*," and though the name appears from the description of the instrument to be its best feature, I scarcely think it was worth getting angry about.

This was followed by an exhibition of negatives taken in the camera upon gelatino-chloride plates, in itself a really interesting exhibit, though Professor Stebbing says he fails to see its value. It is decidedly interesting from a scientific and technical point of view, and proves that good results may be produced on such plates with exposures far shorter than many would be disposed to believe. M. Tondeur must have been quietly chaffing the workers at high pressure—those who invariably make "drop-shutter" exposures—when he said he got better results as regards detail with his five minutes exposures than if he had used gelatino-bromide with exposures of a twentieth of a second. If the "high pressure" men could only take it to heart!

The last and "most interesting subject of the evening," a "new and novel" photo-engraving process, casts a curious old-time shade over the members of the Society who invested it with its interest and the inventor (?) who patented it. I have a full description of the process so far as the production of the engraved plate is concerned, as well as of the machine by which it is engraved, in an account of the exhibits in the 1851 Exhibition. When photo relief blocks first came into use, their application to the process was perhaps a patentable one, and I believe Woodbury did take out a patent. But now I cannot see what there is to patent, or to excite the special interest of the premier Photographic Society of France. I have not seen the

specimens forwarded to the Editors, but perhaps it may be something superlative.

Many landscape photographers will be grateful to Messrs. Spurge and Cowan for their suggestions as to the use of a biconcave lens as a view finder. This is about the simplest and most efficient contrivance for the purpose that I have yet seen mentioned, and at a very small cost might be made to suit any lens and any size of plate if used as a view meter, while for merely locating objects on the plate, without using the focussing screen, it stands unrivalled for simplicity. M. Chevallier's practical rendering of the same idea reported from Paris is very convenient and portable. It consists of a parallelogram of glass with one of its surfaces ground concave, making it a plano-concave lens that will stand on edge on the camera without trouble, and may be carried in the waistcoat pocket without the slightest inconvenience. It is to be hoped something of the sort will be introduced here before long.

Speaking of "finders" leads me to ask the question how they are to be used with some of the ridiculous cameras that have been recently introduced into the market. With an instrument fixed under the waistcoat or in the coat-tail pocket, I fail entirely to see the use of a finder, or even if it could be used, I should like to know how the camera is to be made to answer the will of the operator. Yet the Chinese used to be said to make tolerably fair practice with their matchlocks when fired from the hip.

But the members of the Birkenhead Society have discovered still another difficulty with one of these waistcoat cameras, namely, how a correct level is to be obtained, so as to secure perpendicular lines, when the instrument is used by an operator "with abnormal corporation!" It seems to me that the operator who is clever enough to select and "locate" a picture with such an instrument is not one to be mastered by trifles, and, "corporation" notwithstanding, I would back him to produce lines at any rate straighter than his own.

Theatrical interiors appear to be getting quite the fashion since Messrs. Hyslop and Roberts set the ball rolling once again—for they were not the first by many years to produce such pictures. But why should "an imitation of a Turkish street scene" be selected from among its fellows as "most natural?" Has the term "natural" any reference to the character of the illumination—or want of illumination—of the bazaars and slums of Eastern cities? If so, the criticism is not complimentary to the pictures, as a whole, exhibited at Birkenhead.

After all, publication in the photographic journals does not seem to be of much value, or at any rate it is not esteemed so by those who read papers and those who report them. I can forgive the reader for repeating a formula *vis à voce* to his hearers, but I am not so inclined to be lenient to the reporter who occupies several lines of "displayed" type in repeating it, and gives me the trouble of re-reading it in his account of the meeting. Mr. Wollaston, at the Convention, gave a developing formula singularly resembling the American Standard I referred to last week, and it was duly given to the public in THE BRITISH JOURNAL OF PHOTOGRAPHY the following week. If the JOURNAL is any good at all, where then is the need to repeat it weekly in the same columns, as has been the case for at least the last fortnight? I shall wait until next week for a reply; meanwhile, if any secretary has republished it I hope he will be able to give a good reason for so doing.

MONITOR.

IMPROVING FEEBLE NEGATIVES.*

BEFORE exposing the plate, I have already mentioned that it must be made perfectly dry and warm, and in that condition placed in the printing frame, the sensitive surface being duly protected from mechanical injury, as well as damp, during the period of exposure. In order to learn development it will be as well to practise the reproduction of a negative instead of merely the improvement, as this will give a better idea of the capabilities of the process and better permit the progress of the formation of the image to be watched. We will, therefore, suppose a clean glass plate to have been coated with the sensitive mixture, dried, and, together with a negative, to have been placed warm in the printing frame and exposed.

Upon taking the plate from the frame, if the exposure has been short, it may probably still retain some of the warmth, in which case

the development or dusting process may be at once proceeded with. If perfectly cold, it is imperative; and, in any case, it is safer, before commencing, to again gently warm the plate, in order to ensure its being perfectly dry, as, if it should have absorbed any considerable amount of moisture, the first touch of the brush may produce a mark which will be afterwards indelible, especially if it happen to fall on any of the protected parts of the film. It is well, also, to heat a small quantity of the powder to be employed, in order to ensure that that also is perfectly dry.

The light to be used should be orange or yellow, and plenty of it; the so-called "canary medium" or "golden fabric" will either give a suitable illumination, the translucent surface forming a good background against which to examine the progress of the development. A sheet of clean white paper should be spread upon the table to serve the double purpose of catching the powder dusted off the plate and also to reflect the light through the negative while in a horizontal position. The brush must be a soft one of camel-hair or similar material, of moderate size, so as to hold a fair quantity of powder, and enable it to be spread quickly over the plate. I formerly used a flat brush about an inch in width, but now prefer a round dusting brush fixed in a quill about the thickness of a lead pencil; such may be obtained for about a shilling. A smaller brush may be kept handy for local treatment.

All the necessary arrangements being made, the warm plate or negative is taken in the hand or on a pneumatic holder, and the brush, having been dipped into the powder, is passed rapidly over the surface, backwards and forwards, along and across. A good supply of powder may be applied to the surface, but kept in motion, and never allowed to rest long in one place. At first no apparent effect will be produced, but, as the plate cools, the surface will begin to present slightly dull patches as the powder commences to adhere; and if, after a minute or two, the superfluous colour be dusted off, a faint picture will be visible by reflected light, though probably not when the plate is looked at by transmission.

If the exposure has been correct and the sensitive mixture is in proper condition—that is, contains the proper amount of hygroscopic matter for the state of the atmosphere—all that will be requisite will be to continue the dusting process until the desired degree of density has been attained, always observing that the powder is kept in constant motion and that the brush is kept working pretty evenly over the whole surface of the plate. But it is seldom that the prevailing circumstances are altogether favourable; it is no easier to accurately hit the proper exposure in this than in other processes, but, fortunately, as in others, the development affords a good deal of latitude. The following general hints will give the learner an idea how to proceed in case of any hitch in the proceedings:—

If after some time, say three or four minutes, of diligent dusting no image is formed, or only that visible by reflected light, either the exposure has been very much too long or else the sensitive solution is deficient in hygroscopic matter and the atmosphere is too dry to supply it with the necessary moisture. In such a case the best plan is to lay the plate on one side for a few minutes, first dusting off very carefully all the superfluous powder from the surface. This is important, as, should the film become suddenly tacky, as is very often the case, the powder would become attached, and not only give a spotty appearance, but form a number of nuclei, around which further quantities would settle on resuming the dusting.

After a few minutes' rest the film will, in all probability, have acquired sufficient tackiness to allow development to proceed, but before again applying the brush it is necessary to see that it has not become too moist. First, try the edge of the plate with the finger; if a decided impression is left the plate is too moist and must be redried before proceeding any further. Upon the resumption of the dusting it will in all likelihood be found that the film is not so slow in absorbing moisture as at the outset. If the film take no decided impression from the finger, it may be tested further by passing the brush, lightly charged with powder, round the edges, when, if no tendency be shown to violently attract the powder in patches, it may be passed lightly and rapidly over the whole surface, and the former course of procedure resumed until there is again a stoppage of the action, when a further rest must be given.

* Continued from page 531.

It is the custom with some operators under such circumstances as these to breathe or blow upon the plate in order to supply it with the requisite moisture, but this is a practice I do not recommend, except in very refractory cases, as the action set up is so apt to be irregular and the powder laid on in dense patches. In bad cases of this sort—that is, when the atmosphere is very dry and the sensitive surface deficient in hygroscopic matter—the best plan is to create an artificially moist atmosphere by shutting up the plate in a box or drawer in proximity to a wet sponge or some damp blotting-paper; this will at least promote uniformity of action.

If, on the other hand, the powder commences to attach itself rapidly to the plate, and in a coarse, smeary, and irregular manner, showing the marks of the brush, it is evidence of under exposure, or, what is more probable, excess of hygroscopic material and the presence of too much moisture in the atmosphere. This is a more difficult state of things to cope with than the previously mentioned, and the result rarely justifies the trouble taken; it is better to begin afresh with a new exposure, and, if need be, with a modified solution. All that can be done is to keep the plate as dry as possible by repeatedly re-warming it, but, as may be readily imagined, the game is scarcely worth the candle.

I do not wish to infer that slight cases of under exposure cannot be successfully met in this manner, because, by carefully re-warming, combined with a judicious local use of the brush, they undoubtedly can; and in occasional circumstances, which will suggest themselves as experience is gained in working the process, the method of repeatedly redrying an under-exposed or over-hygroscopic film will prove of great use. It is advisable to have at hand always, when developing, the hot plate described in my last article.

A word or two may be said on the subject of the sensitive solution, and its preservation in a condition suited to the prevailing conditions of the atmosphere. This is a sufficiently easy matter when the process is in constant use from day to day, but not so when it is only taken up occasionally and perhaps at rare intervals. When it is in regular use a simple hygrometer suffices to indicate from day to day the changes, if any, that have taken place, and the modification necessary or advisable in the working solution. But it is impossible to fix any definite proportions of the different materials to suit any particular atmospheric conditions, even if it is feasible to accurately estimate the latter at short notice; hence the amateur must trust very much to experiment. It need not prove a very difficult matter, however, to get the solution into working order if the formula I have given be taken as the starting point. That will suit what I may term normal conditions, and any departure therefrom can readily be discovered by the behaviour of the plate under development.

In preparing the solution, it is, perhaps, the best plan to make use of separate solutions of known strength of albumen, honey, and bichromate, each carefully filtered, mixing them in due proportions when required for use. The mixture does not keep in good condition for many days, hence the advisability of mixing only so much at once as may be required. If on the first trial it should prove to require modification, it is easily effected by the addition of more of one or other of the separate solutions, bearing in mind that the honey is the hygroscopic element.

It is scarcely possible to give any more detailed instructions on the subject of development beyond what I have already said. One or two actual experiments in the process will make perfectly clear the distinction between under and over exposure, and all that then remains for the novice is to always observe a few very simple rules. Always have the solution carefully filtered and the plate perfectly clean and well dusted. Always put the plate warm into the printing frame. Always warm the plate before commencing to develop. Always test the plate as to its hygroscopic condition before reapplying the brush after it has been laid aside. And, lastly, always have everything perfectly dry. If these simple rules be observed the rest will be comparatively easy.

And now turning briefly to the treatment of negatives, the chief value of the process is the facility it affords, when the development is mastered, of local treatment, or the treatment of portions only of a negative. It enables this to be performed in a far more efficient manner than by any system of masking, as the dusting operation places in the hands of the operator a power of "vignetting" one part

into another that he does not otherwise possess. Indeed, I have seen used, and have used myself, the bichromated albumen mixture without any exposure to light, simply as a basis upon which to apply powdered colour for purposes of local treatment and masking, and I am not sure that this application of it alone is not worth serious cultivation.

There is one "dodge" that I have found particularly useful in working on the back of the negative when it is desired to magnify contrast. Give a very short exposure *through* the negative, and develop until there is a fair deposit chiefly on the *lights* of the negative. Now redry and again expose for a *very* short time, but this time let the bichromated side of the plate have the exposure. In this manner the *surface* of the unprotected parts becomes *hardened*, while the deposit already formed on the protected portions retains for them their power of still taking on more powder, and so gaining density. This may be repeated more than once, but it is clear that each individual exposure must be excessively brief—not more than a few seconds.

To finish off the plate when the required effect is gained, let it be once more heated, and then placed in the sun or daylight for some time to thoroughly harden the film. It is then coated with collodion, and afterwards washed until the colour of the bichromate is removed, a very dilute solution of sulphuric acid aiding materially towards that end. It is in view of this washing operation that I advise that the gelatine negative film be not varnished, as it will then better stand the washing. There is no need to varnish the dusted image, as it is exceedingly hard when collodionised.

Should it be desired to remove the image produced in this manner it may be done with a mixture of sulphuric acid and water, one to five, or, if that be not at hand, a *cold chisel*. H. Y. E. COTESWORTH.

WRITING AND DRAWING ON GLASS.

I.

HAVING made a few experiments recently with the object of finding out the best method of producing sketches and handwriting upon glass with pen, lead-pencil, or brush, I propose to narrate the results obtained. The subject is naturally one of interest to photographers, who constantly have to do work of this kind, chiefly in connection with the improvement of negatives. Etching on glass is sometimes necessary, not with hydrofluoric acid, but by coating a glass with an opaque film, and scratching through this with a needle, so as to produce a negative of a line subject, from which positive duplicates can be produced by any printing process. I propose also to describe a novel method of converting a line drawing upon glass into a negative having perfectly clear glass in the lines, and any strength up to opacity in the ground. The same system is also available for producing transparent coloured drawings upon a shaded or opaque ground.

Writing with Ordinary Ink.—When writing on glass is wanted by a lecturer, as a slide for the lantern, the readiest method of doing it would be to use the usual pen and writing-ink on a small piece of clear glass. It is possible to write thus, but the results are extremely imperfect. The ink spreads on the glass so that fine lines cannot be produced at all; if the glass is greasy the ink refuses to take to it, except in blots; and, lastly, the writing is very faint, through the ink not being sufficiently opaque. In order to enable the ink to take more readily to the glass, it has been recommended that the tongue should be applied to the surface, so as to moisten it; when this moisture dries the glass is apparently clean, and writing upon this surface, it is said, can be done with facility with ordinary ink. The method may command admiration on account of its simplicity and readiness, as most people have a tongue at their disposal, otherwise it has few virtues; there is a slight improvement over the first method, and that is all that can be said in its favour. A little ox-gall rubbed on the plate has a similar effect. Gum is frequently added to writing-ink to prevent it spreading upon paper, the amount is small, and is not sufficient to prevent spreading when the ink is applied to glass; hence the addition of a little more gum arabic (or, what is better, white sugar) to the ink causes an improvement in this respect. If a cloth is moistened with the gum solution, and the glass is rubbed with the cloth so as to leave a thin film of gum on the surface, and this film is allowed to dry, the writing will become easier, and it will

be possible to produce fine lines. If, instead of the gum, we employ a film of gelatine, we have again an improvement, and our writing on glass for the first time becomes easy. The gelatine should be dissolved in warm water, in such proportions as to form a thin jelly when cold; the glass having been warmed, the solution may be applied with a brush—the film will dry in a few minutes. A hard gelatine is the best for this purpose, such as Coignet's Gold Label. A soft gelatine is apt to tear up and absorb the moisture from the ink too quickly. The writing produced in this way is not very dark in the lines. The ink that is employed may appear black enough on paper, but on glass, owing to the light only passing *once* through the ink, it proves weak. When the writing is on paper, the light passes through the ink to the surface of the white paper, which reflects it back again through the ink, thus producing by a double passage a greater depth of colour.

The Powder Process.—There is a simple method of producing opaque lines on clear glass, but it is not suitable for very fine work. A glass plate is carefully cleaned from every trace of grease or gum, and is then polished with French chalk. A thin syrup is made by dissolving white sugar in water; if cold water is saturated with the sugar it will be of the right strength. This is used as ink in a pen, by which the writing is done; when the latter is dry it will be nearly invisible. We can now select a fine dry powder of any sort or colour, and dust it over the writing with a soft camel-hair brush. If the sugar is perfectly dry none of the powder will adhere; but if the writing is breathed upon, so as to soften the dried syrup, it will retain the pigment, and the writing will stand out clear and distinct. Powdered plumbago and lampblack may be used for black lines; other colours in powder, such as burnt sienna, gamboge, Prussian blue, &c., will impart colour, but not a transparent colour; while gold, silver, and bronze lines may be produced by dusting over with the various bronze powders sold by druggists. With care, very fine lines may be produced by this system, but they are apt to be obliterated through the softened syrup being carried away by the powder during the act of dusting. If the sugar becomes too much softened by the breath the lines will become blurred; however, the process is very useful and practicable for many purposes. Designs may be cheaply produced in quantity in this way with the aid of indiarubber stamping blocks, such as are used with aniline inks on paper. If such a block is pressed on a pad containing syrup, and then on a clean glass, the design will be transferred in invisible form to the latter, and will instantly start into clearness and vigour when the powder is applied. When the syrup becomes dry, the powder adherent to it will be firmly held, and will withstand a moderate amount of friction. If exposed to damp, however, the writing will be apt to rub off. This may be prevented by applying a protective film to the glass after the writing is completed—this film may be either plain collodion poured over the glass, or mastic varnish put on with a brush, or negative shellac varnish applied in the usual way to the previously heated plate. If the syrup is replaced by a sticky substance insoluble in water, such as jappanners' gold size, or Canada balsam thinned with turpentine, the design, when dry, would be quite unaffected by damp, and would not require any protection on this account.

For fine writing or sketching on glass with a pen, the syrup is the best medium, as it flows easily from the nib. In order to render the writing visible during its production, and before the application of the powder, a little aniline blue or black may be dissolved in the water before adding the sugar, or the syrup may be made by dissolving sugar in common writing-ink.

The same process may be employed on any smooth surface—card mounts, for instance. A photographer can easily put his name or autograph in gold letters on any mount by having a rubber stamp made with the desired inscription, or he can write with a pen dipped in a limpid solution of Canada balsam in turpentine. The writing will be faint at first, but on applying a gold bronze or coloured powder, which will only adhere to the writing, it will become very distinct, and, when dry, will bear handling. This method gives much better results than writing with the gold ink made by mixing bronze powder with syrup or a thin varnish.

The best result of all is obtained by using gold leaf, which is pressed upon the writing as soon as it is set, and then left for some hours to allow the varnish or "ink" to get thoroughly dry. The superfluous gold leaf is then wiped off with a cloth.

A Collodion Film, when dry, is very easy to write upon with a pen and to paint on in water colours. The ordinary enamel or plain collodion may be used, and will be found to give a surface perfectly free from grease, so that the ink will take to it readily. It is not, however, fit for lead-pencil work.

Gum Dammar, dissolved in turpentine or benzole, gives one of the best surfaces for writing upon with a pen, and it has the additional advantage of being available for the lead-pencil. I believe that this gum is more largely employed than any other by retouchers, as a medium for enabling them to work upon gelatine negatives. Care should be employed in the selection of the solvent; some turpentine leaves traces of grease, and this makes the film useless. The rectified turpentine should be employed, or, what is better, the dammar gum may be dissolved in a little benzine, which is then thinned with ether to the proper consistency. This medium flows as easily on glass as collodion, it gives an even film, and it has the advantage of drying quickly, so as to be available for work in a short time. The drier the gum is the better does it take the lead. A little indiarubber solution is added by some to give elasticity to the film; practically the gum dammar alone answers very well.

ALBERT WM. SCOTT.

COLOURING AS APPLIED TO PHOTOGRAPHY.*

THERE is nothing more essential to an artist's securing comfort in his working and completeness in his effects as his *materials*. Above all things they should be good, indeed, the best procurable; they will soon and effectively repay all the extra outlay entailed. I think it is only justice to mention the name of Mr. James Newman when on the subject of materials. He has devoted years of study in order to produce various *spécialités* to aid the artist in his efforts to colour photographs. Among such I may name his "*Diamond Enamel Paste*," which imparts not only a beautiful finish to either plain or coloured photographs, but also a depth and brilliancy, combined with a certain degree of protection against the evil effects of exposure to the atmosphere. It also gives to the photograph a bright surface which hides all offensive touches or markings which would be too prominently observable without its application.

Another of his *spécialités* is his "*Sizing Preparation*," which will be found very useful in many ways. It is most efficacious as a preparation to render the surface of the photograph suitable for working upon. In its natural state it is rather difficult to float colour evenly over the surface of a photograph, and there is usually a necessity for some means or other to give it such a quality as will allow of an even wash of colour being passed over it. For this purpose, therefore, I can recommend this "*Sizing Preparation*." There is a somewhat similar "*size*" for use on absorbent papers, and, if needs be, will produce a surface where same may be injured by over work or the too frequent application of the sponge. The colours, by being slightly mixed with this preparation, will have a great tendency to become fixed, and can be worked over with very little risk of being disturbed, and can be even varnished. I may as well say that my remarks are almost exclusively intended to treat on water colour, although a few may be equally applicable to oil colour as well.

A wash passed over a carbon print will not only make it easy to work upon, but, without giving it a gloss, will add a general brilliancy to it, as well as impart a general delicacy of tone. In fact, these preparations are very useful, and in some cases almost indispensable.

Brushes! Ah! what trouble sometimes to get good ones. The artist should always keep a sufficient quantity by him, and they should be the best. He must have some fine pointed sables for stippling and working out the finer details, and larger ones for working in the washes and broader portions of his picture. There is no rule which can be laid down for the selection of brushes; every one should select those with which he can work with the maximum of comfort, but they should always be the best as to quality. It is quite a matter of taste whether they are mounted in quill or metal. Personally I use the latter, as they stand wear and tear somewhat better.

For very many years (I do not care to say *how* many) I have been in the habit of using Winsor & Newton's brushes, and have invari-

* Continued from page 537.

ably found them really good. Their price is not the lowest, but they don't profess to be *cheap* rather than supply the best article. All sensible men who think a little must know that a really good article is worth a fair price. I have known them rise their prices, and when I inquired how it was they very kindly explained that it was owing to the difficulty in procuring the sable with sufficient *spring* to enable them to provide a first-rate brush. One need never grumble at the price varying a little, but it would be another matter if the *quality* varied. This, I must say, I have never found; their brushes are always well selected, and if they sell you a brush and say it is first-class you can rely upon it. At least, such has been my experience.

I do not wish to infer by this that a *cheap brush* by other makers may not be good, but I do say that such brushes are not dependable. One may be really a good brush, but the next half dozen may be unfit for producing good work.

We should be provided with a china palette, a few saucers, and one or two slanting tiles. When large washes are required it would be impossible to get enough colour mixed upon a palette, and in such cases the saucers or slanting tiles will be invaluable. Indiarubber, ink-eraser, sharp knife, scraper (this instrument may be procured at any colour shop). Some painters use a lancet, while others use a needle. We must also have some very finely powdered pumice-stone, a bottle of gum-arabic water, not too thin, as it can easily be diluted by the addition of a little water. An agate burruisher and drawing pins will almost complete the list of your wants. Of course, if you are engaged on large work I would recommend the use of a *mahl stick*, as its use gives considerable freedom to the hand.

If, again, you paint, in general, large work, an easel will be necessary, and for general work and usefulness a "Cerbould" is undoubtedly the most desirable. But any easel, if sufficiently firm, will answer the purpose quite well enough. For the smaller work, however, an easel will be somewhat awkward, although one can get into the habit of working at one to such an extent that they will prefer painting even the smaller work upon it, pinned to a drawing board. I think a desk suitably placed upon a table will be found more convenient, notwithstanding, for the smaller work. I may here mention that a small pot of prepared ox-gall will be found very useful at times. It is not necessary to use it on ivory, but it is often almost indispensable for paper that appears somewhat greasy. The less, however, used of it the better, as too much will have a ruinous effect upon the photograph or paper. Any subject which seems to require it should have a weak solution of it washed gently and quickly over the entire surface with a camel-hair pencil. Camel-hair pencils are no use for painting generally, as they have not sufficient *spring* to give a reliable *touch*. Some prefer red sables to all others on account of their greater stiffness, although the brushes made of black sable invariably have better points. The small sables used for stippling should not be too small, as working with such would lead to an excess of finish or rather fineness of stippling, which would materially injure the higher objects of art, viz., depth, solidity, and colour.

We now come to the most important part of all—the colours. As in the case of the brushes, I have ever given the preference to the colours produced by Winsor & Newton. I have never found them vary, and have always found them easy and agreeable to work with. I mostly use moist colours, and have always found those supplied to me by Winsor & Newton, although they retain their moisture in the box, dry consistently and in convenient time when applied to the picture. These are both qualities which recommend themselves to the artist using them, and I feel sure any adopting their use will derive complete satisfaction therefrom.

I will give a list of colours used in miniature painting, with a few words as to their properties and uses, and supplement them with such others as would allow of every class of colouring being carried out.

Carmine.—A brilliant crimson, possessing great power in its fuller touches, its paler washes being possessed of considerable clearness, though not quite equalling rose or pink madder in this latter quality. It is easy to work, but is somewhat fugitive.

Pink Madder.—A most delicate carnation, much used on account of its superior permanency. It is much clearer than either crimson, lake, or carmine in its lighter tints, but is not possessed of density.

Rose Madder is similar to pink madder, and is possessed of a little more depth.

Crimson Lake possesses much of the characteristics of carmine, but lacks its extreme richness and brilliancy. A most useful colour for mixing in various tints for draperies, &c.

Venetian Red.—A most beautiful as well as permanent colour. A beautiful colour for flesh. Its tints, if not bright, are always clear, and in combination with cobalt or French blue will produce fine pearly greys. It works better than light red, and is a better and more delicate tint.

Light Red.—A clear and transparent red, low in tone, more of an orange tint than Venetian red, but otherwise similar in character. Makes a good ground for flesh.

Indian Red.—A powerful red of a purplish hue. It is an excellent colour for the shadows of the flesh either alone or in combination with blue.

Vermilion.—Rather a heavy colour, and very little adapted for use in flesh tints. It does not flow well, and is not transparent, hence it is not so generally used as it otherwise would be.

Scarlet Vermilion.—More scarlet in tint than above, and washes much better.

Orange Vermilion.—Rather more transparent than the others, with a clear but not bright orange hue. Washes moderately well. Some miniature painters hold it in great esteem.

Chrome Yellow is an opaque or body colour. Very necessary for some effects, such as bringing out gold, &c. There are three tints of this colour—pale, deep, and orange. For miniature painting the lightest tint will be of sufficient depth.

Indian Yellow.—A beautiful intense yellow. It works well and is permanent. Mixed more or less with Venetian red can be used for a flesh. Is also very serviceable for draperies, &c.

Roman Ochre.—Used for dark flesh colour and also draperies. For these purposes is much preferable to yellow ochre.

Gamboge.—A pale and somewhat greenish yellow, sometimes used in draperies.

Cadmium Yellow.—A nearly transparent colour. Best vehicle for procuring an orange tone. A most brilliant and powerful yellow.

Ultramarine.—Permanent, but does not work well, except in large masses of drapery. It is one of the most permanent colours we have, and is most pure in tint. It is not so well adapted for mixing with other colours as the other blues, owing to its gritty quality.

Ultramarine Ash is not so positive in tint as ultramarine, but washes better; it is sometimes used in flesh.

Cobalt.—Most useful in every respect, sufficiently bright, permanent, and washes well. Cobalt in conjunction with pink madder and raw sienna will form a flesh.

French Blue.—Darker than cobalt and of great intensity, is permanent, and resembles the tint of real ultramarine. Although not so pure or vivid, generally it is more useful, for it washes and works well.

Indigo.—Useful for dark compound tints.

Prussian Blue.—Used in miniature draperies, useful to portray blue velvets, and when mixed with carmine all the varieties of purple, violet, and marone velvets can be obtained. REDMOND BARRETT.

(To be continued.)

ON THE FADING OF SILVER PHOTOGRAPHS.

I.

NOTWITHSTANDING the large amount of information which, from time to time, has been published respecting the permanence of auro-argentic photographs, there still remains much to be learnt before we can arrive at a precise knowledge of the *whole* of the causes which combine to change and ultimately destroy them. And even were these causes fully understood, it is obvious that some of them are not under our control, whilst others, by proper care in selecting and compounding the necessary materials and in conducting the various manipulations, can be easily avoided.

It is hardly necessary at the present day to enlarge on the decay-inducing causes which are under our own control. These may be briefly summed up in the use of impure materials, imperfect elimination of hyposulphite, impure mounts, easily decomposed mountants, and, lastly, the storing of such prints in positions where impure air has access so them. It may be stated generally that sulphur and

some of its compounds are the most common and, at the same time, the most potent agents in the destruction of silver photographs. Now these may be communicated to them in several ways. First, from a decomposition of the hypo in which they are fixed; second, from an imperfect removal of the fixing agent by thorough washing; third, from the action of sulphurous fumes derived from the air of the place in which they are stored; and, lastly, from some of the antichlor-hyposulphite of soda not having been eliminated from the paper composing the mounting cardboard.

When Herschel discovered and first described hypsulphite of soda (in the year 1825, I think), he particularly called attention to the fact of its forming an easily decomposed double salt with silver compounds—the chloride for instance. Under such circumstances, if we dissolve two equivalents of silver chloride in one of hypsulphite of soda, we obtain two equivalents of chloride of sodium and one of hypsulphite of silver, thus:—

Now this latter compound (hypsulphite of silver) is most easily decomposed, either by very gentle heat or by even the weakest acids. The consequence is that sulphurous fumes are set free to react on the photographic image and eventually destroy it. For this reason it is important that fresh solutions of hypo should be used for fixing each batch of prints, and, further, that this solution should be neutral or preferably slightly alkaline. Further, to avoid risk of decomposition, every trace of silver nitrate should be eliminated from the prints before they are fixed, inasmuch as the addition of this salt, even in minute quantity, to hypo solution is almost certain to liberate sulphurous acid, which will, of course, react prejudicially on the silver image. But this acid, although it ranks in the list of bleaching agents, if its action be long continued, seems to exercise, also, a deteriorating influence on the paper itself; but whether this be due to its original composition or to some chemical change effected by the silver nitrate, is a question worthy of full investigation. Be this as it may, the fact remains that even the most carefully executed silver print, on plain paper, has its high lights dimmed by the action of this gas. When albumenised paper is the supporting medium, the yellowing effect of the gas is much more decidedly marked, more especially when the air is moist. But this might be expected when we bear in mind the fact that albumen itself contains sulphur, although this quantity varies considerably according to the source from which it is derived. Indeed, albumen is a very complex compound, its composition, according to Liebig, being represented by the following chemical formula:— $\text{C}^{216} \text{H}^{388} \text{N}^{51} \text{S}^2 \text{O}^{68}$.

Mulder and Lieber-Kühn give slightly different formulæ, but all agree in about two per cent. of sulphur.

With albumen, silver forms a compound called albuminate of silver, having, according to Watts, the formula:—

If any one tries the experiment of subjecting to hydrosulphuric acid fresh albumen coagulated by heat and albumen precipitated by silver nitrate, the latter being fixed in hypo and then thoroughly washed, he will find a considerable difference in the effect produced. The plain albumen, so acted on, will remain perfectly white long after the silvered portion of the same albumen has become quite a dingy yellow. To my mind this proves that hypsulphite solution does not altogether remove the silver from the albuminate of that metal, even although the compound has not been subjected to luminous influence so as to suffer reduction. If these experiments of mine with albumen be confirmed, the question would arise whether it would be judicious to continue the use of albumenised paper for silver printing, seeing that such photographs are more liable to decay than when made on specially-prepared plain paper. If we substitute gelatine for albumen we may only be walking out of the frying-pan into the fire; for it also contains sulphur in its composition, but whether in a form wherein it is affected by silver nitrate I have not yet ascertained.

GEORGE DAWSON, M.A., PH.D.

THE FIRST INTERNATIONAL PHOTOGRAPHIC EXHIBITION IN ITALY.

THE International Photographic Exhibition in the fair city of Florence is now open; it is of special interest because it is the first one of an international character which has been held in Italy, and it has resulted already in the founding of the first Italian photographic society. The lack of organization among Italian photographers was one difficulty in the way of holding an exhibition, since it threw much extra work upon the promoters in the way

of bringing their own photographic countrymen together; another impediment was the fact that some of the Italian photographers are saving the best specimens of their work for the Paris Exhibition of 1889.

The Exhibition was opened by the King and Queen of Italy, who were conducted by the president of the managers, Commander Nobili, over the galleries, some of which, thanks to the climate, are in the gardens of a hospital, and some in salons. All the exhibits of Italian amateur photographers, and of persons residing outside Italy, are in special salons.

From M. Léon Vidal's report in *Le Moniteur de la Photographie*, and from a report by Dr. Gioppi in the *Journal de l'Industrie Photographique*, we learn that neither money nor work has been spared to make the Exhibition attractive and interesting, and that the exhibits number 350. In exhibits from outside Italy, France and Germany take the lead. The United States has but one representative among the exhibitors; M. Carlos Relvas sends a fine collection of pictures from Portugal; the Topographic Institute of the Low Countries has sent a very interesting series of exhibits. One of the great features of the Exhibition is the collection sent by M. Nadar, of Paris, which fills the whole of one salon, and is fitted up with perfect taste. It includes varieties of apparatus, also some portraits nearly three yards long upon Eastman paper, and of magnificent execution; there are also several good portraits of Chevreul in various positions, and some interesting photographs of Underground Paris; also a long series of portraits of French celebrities.

From England the Woodburytype Company has sent specimens of its work. Mr. A. Cowan has forwarded some of his gelatino-chloride lantern slides, which occasionally have been projected upon the screen, and were much admired. Some marine views have been contributed by Auty, of Tynemouth, and by West & Son, of Southsea; the former also exhibits two fine prints of a flash of lightning. Messrs. Marion and the Eastman Company exhibit their products. The phototypes of M. Bruckmann are stated to be marvels of good work; M. Bette, of Berlin, is an exhibitor; M. Schuster, of Berlin, exhibits photo-engravings; Dr. Just, of Vienna, bromide enlargements; Dr. Donadieu, of Lyons, furniture, interiors, and decorative designs; and M. Tissandier, photographic proofs turned out in the ordinary printing press. Dr. P. Richter and M. Lönke exhibit photographs taken at the Salpêtrière of the features of certain diseases; Thury and Amey their celebrated shutter; Anschütz, of Lissa, instantaneous pictures of horses at full gallop; Pietsch, of Switzerland, and Debas, of Madrid, landscapes; and De Meyer, of Kief, Russia, some good transparencies. There are exhibits from Constantinople and Barcelona. M. Reutlinger sends some fine specimens of artistic photography to aid painters; the subjects are children, young women, and so on. Among the French expositors of apparatus and materials are M. Darlot, M. Mackenstien, the Paris Central Society of Chemical Products, and M. Tailfer. Voigtländer exhibits lenses; Bussler, of Berlin, elegant columns and statues in *papier mâché* for studios; and M. Français, his last novelty, the '*kinégraphie*.' M. Boissonas, of Lyons, and M. Beernaert, also Mrs. Van Monckhoven, send specimens of their dry plates. Dr. Liesegang exhibits panoramic apparatus for tourists.

The literature of photography is represented by its newspapers and periodicals, and by the numerous works on photography issued by French and German publishers.

Among Italian exhibitors Giardelli, of Florence, sends phototypes; Paganori, photo-engravings; Turati, of Milan, some important prints from type-high blocks, produced by a patented process; Lamperti and Garbagnati, of Milan, tourist and other cameras; Brogi, magnificent photographs on glass; Pallavinci and Sobacchi, of Lodi, portraits cut by the sand-blast; Garofali, Martorelli, and Mosconi, of Milan, apparatus and cards; Colombo, of Milan, and Cappelletti, of Florence, cameras; well-made burnishers and rolling presses by Casalegno, of Turin; a student's microscopic camera by Corsi, of Florence, engineer; ceramic photographs by Bucciolini, of Florence; porcelain vessels by Ginori; dishes, bottles, and measures, by Alman, of Turin; popular Italian dry plates by Dringoli, of Empoli. Capelli, of Milan, and Melszo, of Naples, exhibit their dry plates; Ghezzi, crystallographic prints; Bardelli, of Turin, compact apparatus for Alpine explorers; and Muffone, pocket apparatus. A *salon* is reserved for portraits by Alinari, Alvino, and other Florentine photographers. Among Italian exhibitors are also Brogdi, Rossi, Montabone, and Bettini; the firm of Trèves Brothers exhibits good specimens of photo-mechanical printing, type-high; and the Military Geographical Institute of Florence exhibits work which deserves special study. M. Léon Vidal mentions various Italian commercial firms which do good work in photo-mechanical printing, but adds that it is not equal in quality to that of the best German houses, such as Bruckman, of Munich, Rommel, of Dresden, and Rumler & Jonas, of Leipzig. He

adds that photo-engraving in half tone is but little practised in Italy, and that at the Exhibition the best work of this kind is the magnificent exhibit of the Photographic Society of Berlin. Ceramic photography is little worked in Italy, and, so far as he could see, not upon an industrial scale. The aristotype pictures on view are of good quality; several platinum prints are on view—notably, the artistic specimens by M. Debas. There are very few carbon prints in the Exhibition.

Among the most active members of the Executive Committee are the President, Commander Nobili, Count Bastogi, and Signor Carlo Brogi. At a banquet, after the labours of the jury had been completed, the President said that the Exhibition ought to be the occasion of the foundation of an Italian Photographic Society, and all the persons present at the banquet signed their names as its first members. Count Bastogi was nominated President of the Society, and M. Paul Nadar and M. Léon Vidal corresponding members.

At present it is too hot for Italy, but Florence being a hill town, the heat there is not so fervent. Later in the season this Exhibition should be much visited by English tourists, despite the numerous other exhibitions and attractions in the city.

The mysterious statement about some of the photographs being placed in gardens, no doubt refers to gardens surrounded by colonnades or cloisters, which are common in connection with large Italian buildings, to give protection from the fierce rays of the summer's sun. For the same reason the streets in Italian towns are commonly narrow, or when broad are frequently provided with colonnades. English visitors do not always avail themselves of the protection, perhaps from force of habit, hence the Italian saying:—"Dogs and Englishmen walk in the sun."

A SEARCH FOR A SUBSTITUTE FOR HYPO.*

HAVING tried these experiments upon silver bromide, it was natural that the iodide also should receive some attention. Using the same quantity of silver solution, but precipitating it with potassium iodide in the same careful manner to avoid an excess of the alkaline haloid, washing and draining, there was obtained for each experiment 0.5725 gramme (8.835 grains) of silver iodide. Starting with the usual hyposulphite solution (1 in 6), it required 78 cubic centimetres ($2\frac{3}{4}$ ounces) of it to give complete solution of the silver iodide (0.5725 gramme). Hence 1 part of silver iodide requires 22.7 parts of hyposulphite for solution in a bath of 1 in 6.

Another bath of hyposulphite, twice as strong as that given above, was now tried, and it required 37 cubic centimetres ($1\frac{1}{4}$ ounces) of it to give a solution of the same quantity of silver iodide. Therefore 1 part of silver iodide requires 21.5 parts of hyposulphite for solution in a bath of 1 in 3. It would therefore appear that there is no economy in hyposulphite used in strong solutions when silver iodide is considered.

As in the case of silver bromide, ammonia solution has no perceptible solvent action upon silver iodide. However, a bath was made containing one-sixth hyposulphite and 4.87 per cent. of ammonia, and this was used as a solvent for the silver iodide. It required 67 cubic centimetres ($2\frac{1}{4}$ ounces) of this solution to dissolve 0.5725 gramme (8.835 grains) of silver iodide. Then 1 part of silver iodide requires 19.4 parts of hyposulphite for solution in a bath of 1 in 6 containing 4.87 per cent. of ammonia. Here is a slight gain (about 11 per cent.) in the use of ammonia, and although not as great as in the case of silver bromide, yet under some circumstances it may be of advantage.

Ammonium acetate in a solution containing 30 per cent. of the salt, and slightly alkaline with ammonia, had no appreciable solvent action upon silver iodide. But when ammonium acetate is used in a solution containing one-sixth of hyposulphite and 15 per cent. of the acetate (slightly alkaline with ammonia), it required 68 cubic centimetres (about $2\frac{1}{4}$ ounces) of the mixture to dissolve the above-mentioned quantity of silver bromide (0.5725 gramme = 8.835 grains). This is practically the same result as that obtained by the addition of ammonia to the hyposulphite.

The effect of other admixtures with the hyposulphite was also tried with negative results. In some cases the mixing of another salt with the hyposulphite actually decreases the solvent power of the latter. Calcium acetate was tried as a solvent, both alone and mixed with hyposulphite. Alone, in a solution of 23 per cent., calcium acetate has no perceptible solvent action upon silver iodide. Mixed with hyposulphite solution so that the mixture contained one-sixth hyposulphite and $11\frac{1}{2}$ per cent. of calcium acetate, it decreased the solvent power of the hyposulphite so that it required more than 30 parts of sodium hyposulphite (in a bath 1 in 6) to dissolve 1 part of silver iodide. The same is equally true if sodium acetate is used; this also retards the action of the hyposulphite. A mixture of sal ammoniac (ammonium chloride) and sodium hyposulphite acts in about the same manner, although not so badly, solution being obtained, but very slowly. Ammonium carbonate also, when mixed with hyposulphite, also decreased the solvent action of the salt upon silver iodide, requiring about 30 parts of sodium hyposulphite to every part of the silver haloid.

* Concluded from page 540.

Two other compounds were tried upon silver iodide, for this appears to be the most insoluble of all the silver compounds with which the photographer has to deal, and it would be a great boon if some better solvent than hyposulphite of sodium could be found for it. A solution of sodium sulphite was made containing 1 part of the salt in 4 of water; but it had no perceptible solvent action upon silver iodide, even with the addition of a little ammonia.

Ammonium sulphite in a solution containing 1 part of the salt in 3 of water, had no apparent solvent action upon silver iodide, addition of ammonia making no change. But on adding a solution of sodium hyposulphite (1 in 3) complete solution was obtained after adding 50 cubic centimetres, the mixture already containing 50 cubic centimetres of the ammonium sulphite solution. It requires, therefore, about 30 parts of hyposulphite in a solution 1 in 6, with about 16 per cent. of ammonium sulphite to dissolve 1 part of silver iodide.

There are a few practical results that can be drawn from these imperfect and incomplete experiments upon the solubility of silver haloids. In the first place, there is the determination of the fact (already known in a general way) that silver iodide requires 7.8 times more hyposulphite for its solution than silver bromide in a bath of 1 in 6. Second, addition of ammonia to the fixing bath increases the solvent action of the hyposulphite so that nearly twice as much silver bromide and 11 per cent. more silver iodide are dissolved than when ammonia is absent. Third, that the addition of certain salts to the fixing bath decreases the solvent action of the hyposulphite independently of dilution. Fourth, that the action of the different salts in the fixing bath is materially different with the two haloids.

How the various additions to the hyposulphite act when applied to the fixing of plates and prints I have not yet been able to determine, but hope to do so in the future. The question up to the present time has been: Is there anything we can use, either wholly or in part, as a substitute for sodium hyposulphite? At present there is nothing so harmless and so cheap as this now almost universally used sodium salt; but the many drawbacks to its use lead me to believe that something better may be found by diligent searching. And it would appear that some such experiments as these I have briefly reviewed are steps in the right direction. At some future time I hope to have the honour of presenting to this Association a continuation and amplification of the results here noted, and hope that others will be found able and willing to work in the same field.

This, then, is a kind of report of progress in a line of experimental work that has engaged my attention during spare hours in the past year. I know it is very incomplete, I know there is little that is practical in it at present, but I am satisfied that work of this kind is needed in photography. There is room for a hundred workers upon this and allied questions in photographic science, and if I shall have interested but one of you to take up some work of this kind, I shall be fully repaid for the time I have taken to bring before you this imperfect report upon a series of experiments that have given me great pleasure in prosecuting.

ARTHUR H. ELLIOTT, Ph.D., F.C.S.

THE BRITISH ASSOCIATION.

THE first General Meeting of this Association for 1887 was held on Wednesday evening in the Free Trade Hall, Manchester, which was filled with a large audience, including the leading scientific men in this country and many distinguished foreign savants. Sir Henry E. Roscoe, President, delivered his inaugural address, in course of which he made fitting allusion to the services rendered to science by two of their townsmen—Dalton, the chemist, the discoverer of the laws of chemical combination, the framer of the atomic theory upon which the modern science of chemistry is based, and Joule, the determinator of the mechanical equivalent of heat. "It is well, therefore," said he, "for us to remember, in the midst of the turmoil of our active industrial and commercial life, that Manchester not only well represents the energy of England in these practical directions, but that it possesses even higher claims to our regard and respect as being the seat of discoveries of which the value not only to pure science is momentous, but which also lie at the foundation of all our material progress and all our industrial success. For without a knowledge of the laws of chemical combination all the marvellous results with which modern industrial chemistry has astonished the world could not have been achieved, while the knowledge of the quantitative relations existing between the several forms of energy, and the possibility of expressing their amount in terms of ordinary mechanics, are matters which now constitute the life-breath of every branch of applied science. For example, before Dalton's discovery every manufacturer of oil of vitriol—a substance now made each week in thousands of tons within a few miles of this spot—every manufacturer had his own notions of the quantity of sulphur which he ought to burn in order to make a certain weight of sulphuric acid, but he had no idea that only a given weight of sulphur can unite with a certain quantity of oxygen and of water to form the acid, and that an excess of any one of the component parts was not only useless but harmful. Thus, and in tens of thousands of other instances, Dalton replaced rule of thumb by scientific principle. In like manner the applications of Joule's determination of the mechanical equivalent of heat are even more general; the increase and measurement of the

efficiency of our steam engines and the power of our dynamos are only two of the numerous examples which might be adduced of the practical value of Joule's work."

Professor Roscoe's address had mainly reference to chemical progress, and at the close he observed that up to the present time 3568 members and associates had joined, while the money received amounted to 4000*l*. These were the highest figures in both respects which had ever been reached in the history of the Association, and he had no doubt that before the meeting concluded they would have over 4000 members and associates present.

Our Editorial Table.

PHOTOGRAPHIC PRINTING METHODS.

By Rev. W. H. BURBANK.

In this volume, which forms one of *Seorill's Photographic Series*, New York, the author disarms ordinary criticism by his honest announcement that the work is rather one of compilation than of original research, and that "the opening chapters on the theory of light and its action on sensitive compounds are merely condensed from Abney's *Handbook of Photography*."

The plan of the book is to devote as nearly as possible a chapter to each method or system of printing, compiling and grouping under each all, or almost all, accessible formulæ which refer to it, and coupling with any definite statement made respecting it the name of some one responsible for such. We confess that we should have liked better had the author allowed more of his own *personnel* to appear throughout the work.

The mere mechanical labour in collating the formulæ from photographic *Almanacs* and other works of reference cannot have been small, and the reverend author is entitled to much credit for the manner in which he has carried into effect his intention as expressed in the preface: "The author has aimed to collect, in easily accessible form, information and formulæ connected with the production of photographic prints."

Mr. G. Hanmer Coughton has contributed to the work a practical article on *Finishing Permanent Bromide Enlargements*, which we here introduce:—

"In working upon drawing-paper, from life or from photographs, the paper chosen is one that is strongly sized, because a higher degree of finish can be obtained upon such a surface. In the necessary manipulations of preparing the paper for solar prints—the developing and fixing and subsequent washing—the sizing of the paper is entirely washed out; it is so with the platinum print, the hot developer taking the size out of the paper and making it as soft and absorbent as blotting-paper. With a permanent bromide print, although it has to undergo all the manipulations of development, fixing, and washing, the gelatine surface is not removed, and when dry serves as a strong sizing to the paper. This necessitates a somewhat different method of treatment than upon the softer paper, but all the manipulations for producing an artistic effect upon solar or platinum prints can be followed upon permanent bromide, and from my years of experience I can say confidently that the best results can be obtained quicker and better.

"*Crayon Finishing*.—The only difference is in the material used. Instead of using a stumping sauce alone, I find a mixture of No. 1 Conti Crayon, finely crushed with an equal quantity of crayon sauce, the best for all stumping purposes. Most crayon artists put in their background with a chamois leather. You cannot use a chamois skin upon permanent bromide paper, but a soft tuft of cotton is just as effective and can be manipulated in exactly the same manner; then the fingers can be used as a stump, and the background graded with the above mixture, worked with the fingers quicker and better than with the stump. If you should get your background too dark or uneven, lay the picture flat, sprinkle a little pumice powder over it and rub lightly with the fingers all over, using more powder where you wish your background to be lighter.

"The stumping of hair, shadows in drapery, &c., can be done with a paper stump with the mixture above, in exactly the same manner as upon any other paper, with the difference that the print being so much more perfect in gradation and more brilliant than a solar, there is not near so much stumping needed. In fact, a good permanent bromide enlargement needs very little stumping, the principal work being sharpening and deepening with the point, and flat tints with the mixture, over drapery, &c. The shadows of drapery can be deepened with Nos. 2 and 3 Conti, in the usual manner, softening and grading with the finger or stump.

"The use of rubber and ink-eraser for taking out lights is well known to crayon artists. The same method of taking out the lights can be used on permanent bromide paper and with greater effect, for the lights can be taken out cleaner and with greater facility than upon absorbent paper, where the crayon is rubbed right into the fibre of the paper. Another advantage is that you can use the scraper upon these prints for taking out lights and even lightening dark places. With a sharp scraper lights can be taken out in lace, white draperies, &c., giving great brilliancy without

abrading the paper, for the picture being entirely upon the surface, you can scrape quite through the deepest tint before reaching the paper itself.

"The finishing of the face must be done with a harder crayon than usual, as the harder surface of the paper requires a harder crayon to work upon it. The best for the purpose is No. 0 Conti superfine in wood. A No. 1 of the same kind will also be required for the darker touches. This work upon the face is more in the manner of mending and joining gradations than the usual work upon the solar, and it is in this respect that a permanent bromide print is so much superior to any other, and requires so much less work, while the result is much finer.

"*Pastel*.—With the pastel there is no difference in the manipulations, the gelatino-bromide taking pastel with the greatest facility.

"*Water Colour and India Ink*.—For water colour or ink it will be necessary to wash the surface of the print with a weak solution of ammonia till all the greasiness disappears, and to be careful not to wash one colour over another till the first is thoroughly dry, not alone surface dry, but be careful that the gelatine is dry before washing over the same place, or blisters may result.

"*Note*.—In case any paste has been allowed to get on the face of the print, in mounting, it should be washed off with tepid water and a soft sponge, and the print allowed to dry thoroughly before any crayon work is done on it.

"It has been found by experience that prints take the crayon better if they have been dried and afterwards soaked in water before mounting. The preliminary drying hardens the film."

The work contains two illustrations, a frontispiece by the excellent engraving process of Mr. Edwards, of the Photogravure Company, New York, and a bromide print from an Eastman film negative. The typography and general get-up of *Printing Methods* leave nothing to be desired. The price is one dollar (four shillings and twopence).

PATENTS COMPLETED.

A NEW OR IMPROVED POCKET OR PORTABLE APPARATUS FOR THE TAKING OF PHOTOGRAPHIC PICTURES.

No. 12,571. WILLIAM JAMES LANCASTER, Colnacre-row, Birmingham.—
October 4, 1886.

My invention has for its object the production of an extremely portable apparatus for the taking of photographic pictures, and which said apparatus may be made either in the form of a watch or chronometer case, tobacco box, match box, cigar or cigarette case, purse, locket, charm, or other like article, by which means a person is able to carry a complete photographic apparatus in a very small compass.

I will describe my invention in connexion with a watch or chronometer case to be carried in the pocket or about the person.

I take an ordinary watch case having a hinged closing front or lid which is automatically opened by pressure applied at the side or at the loop part, which liberates a catch bolt, and so allows the enclosing lid to fly open.

Within the hollow of the body of the case the camera is situated, which consists of a number of short tubes working telescopically one within each other, so as to render the same collapsible when not in use. The back tube of these series of tubes, which is of larger diameter, is secured loosely within the inner edges of the open front of the case by a flange connexion, and within the inside of this telescopic body a coiled spring is enclosed which automatically distends or opens out the camera body on the lid of the case being opened. The lens is secured within the last or outward tube, while the dark slide, which contains sensitised paper, gelatine sheets, or prepared plates, is disposed at the back.

The focussing of the lens may be done by any suitable adjusting expedients or by hand.

The dark slide consists essentially of a flat case with folding overlapping doors having spring hinges which automatically open the said doors on a catch or other fastener being liberated. The catch fastener consists simply of a button or turn, which on being rotated is made to engage with or be disengaged from one of the doors.

The back of the enclosing case is pierced with a hole suitable for the reception of the frame of what is commonly known as the dark slide, and which is held in position by rotating turns or catches moved in and out of position preferably by hand.

In using the instrument or apparatus in order to take a portrait, simply press the releasing catch of the enclosing lid, when it automatically flies open and allows the body of the camera (and lens within its front) to be distended to its fullest extent by the expansion of the enclosed coiled spring.

After focussing, a button or turn at the back of the case is rotated, when the doors of the dark slide automatically fly over, and so present the sensitised surface or plates enclosed within.

After sufficient exposure has been allowed, the lid of the enclosing case is simply closed, when the collapsing body of the camera and the lens at its end is folded up and enclosed within the body of the case, when the negative can afterwards be removed from the dark slide, and placed in a printing frame as usual.

The apparatus or appliance is principally applicable for taking instantaneous photographs for detector purposes.

The bellows constituting the body of the camera may be formed gusseted, when made of leather or indiarubber, or the said body may be made of a coiled riband spring with the coils or involutes working telescopically one within each other.

Instantaneous shutters may be provided at the lens end of the photographic apparatus, or at the dark slide end; in the latter case, the shutters or doors are made to instantaneously open and close by an automatic or other device, which may be regulated to any predetermined exposure as may be necessary.

The application of my invention to other articles, such as purses, cigar and cigarette cases, lockets and other pendant articles, differs in no essential respect to a watch case as already described.

The claims are:—1. The means herein described of taking photographic pictures, by combining with a watch or chronometer case, cigar or cigarette case, tobacco box, match box, purse, locket, charm, or similar pocket or pendant article, of a photographic apparatus. 2. The combination with a watch or chronometer case, cigar or cigarette case, tobacco box, match box, purse, locket, charm, or other similar pocket or pendant article, of a photographic apparatus, constructed, arranged, and worked substantially as described and set forth. 3. Making the camera bodies, of portable photographic apparatuses of the kind herein described, distend themselves automatically, on the front cap being opened, as described and illustrated. 4. Providing "dark slides" or boxes for holding photographic sensitised plates, films, or paper, with spring hinged folding doors, or shutters, and which said boxes are constructed, and the doors or shutters held (closed) and liberated by means herein described and illustrated.

IMPROVEMENTS IN MACHINES FOR COATING PHOTOGRAPHIC PLATES.

No. 12,700. BENJAMIN JOSEPH EDWARDS, The Grove, Hackney, London.—
October 6, 1886.

To provide improvements in certain parts of the machine for coating photographic plates with gelatine emulsion, for which letters patent were granted me in 1884, No. 8643, or in other machines for the same purpose.

The improvements are designed—1, To effect more perfect contact between the distributing roller and the edge of the scraper which carries the emulsion to the plates; 2, To effect the more rapid and perfect setting of the emulsion or cooling of the plates when coated; 3, To provide travelling bands of greater utility and durability for carrying the plates; 4, To effect the more perfect cleaning and drying of the backs of the plates, together with greater facility of working and saving of time and material; 5, To provide for colouring the backs of the plates; 6, To effect the removal of particles of dust from the surface of the plates previous to coating.

I effect the improvements in the scraper by introducing a separate adjustable blade of indiarubber or other suitable material of a soft and yielding nature, which is inserted in or attached to the metal scraper and may be removed from time to time as required.

I effect the improvements in the cooling of the plates and setting of the emulsion in the following manner:—In place of the continuous close tunnel or cooling chamber as described in my former specification, through which the plates are made to pass, I construct the roof of the said chamber of a series of bars, which may be of the form of the letters S or Z, and upon a grid formed by these bars I place lumps of ice. I fix the bars in such proximity to each other and incline them at such an angle that they shall carry off the water from the melting ice and also the water of condensation which forms on their lower surfaces, and at the same time allow for the passage of a current of intensely cold and partially dried air to the plates as they pass underneath.

To provide improved travelling bands for carrying the plates I do not alter the general construction of the ordinary woven wire band which I have hitherto employed, further than to insert two or more wires which may be somewhat stouter than the rest, which are woven in and run the entire length of the warp, and I cause these wires to be woven over cross wires of suitable thickness at short intervals. The cross wires being afterwards withdrawn, each of the stouter wires is left, forming a row of projecting loops upon which the plates rest slightly above the surface of the rest of the band. If preferred the loops may be formed in the web instead of the warp.

To effect the improvements in cleaning and drying the backs of the plates I make use of a similar arrangement to that described in my former specification, but I make the surface of the cleaning band of soft cloth, felt, woollen velvet pile, or other suitable material, and I arrange it to pass over one or more rollers, so adjusted that the under side of the coated plates shall rest upon and be drawn or pushed (by the action of the travelling band) over its surface while it is made to travel slowly in the opposite direction. Thus any emulsion which may have escaped on to the backs of the plates is removed on to the band which passes through a tank (through which a stream of hot water is kept constantly flowing) before coming again into use. More than one cleaning band may be employed if desired. To remove any excess of moisture I arrange one or more strips of indiarubber, or other suitable material, to act as a scraper or squeegee, over the edge or edges of which the plates pass as they enter the cooling chamber.

The above-described cleaning apparatus may be dispensed with altogether if desired when my improved endless wire bands, as specified above, are employed, in which case any emulsion which may have escaped on to the backs of the plates is dried on, and, if necessary, afterwards removed by hand or by other convenient method.

In order to keep the cleaning band (or in the event of the travelling bands only being used to keep these) as clean as possible, and also to economise the material used, I employ a narrow trough or receptacle of porcelain, glass, or metal, which I fix immediately below the lower edge of the scraper or distributor, from which the emulsion flows on to the plates, keeping its upper edge slightly below the surface of the travelling bands, space being obtained by arranging the rollers over which the bands pass (as described in my previous specification) so as to allow for the insertion of the trough. Thus any of the emulsion which escapes is caught by the trough and may be used again.

To provide for colouring the backs of the plates I employ one of the cleaning bands (if more than one is provided) or I arrange an additional band of similar construction, and by passing it through a solution of suitable colouring material I carry a portion of it to the backs of the plates and thus prevent the defect in

photographs on glass known as halation. When the colouring band is employed the squeegees are dispensed with.

To effect the removal of particles of dust from the surfaces of the plates before coating I employ a revolving or stationary brush secured immediately in front of the distributor, so that the plates shall be brushed as they are drawn or carried by the band into the machine.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
September 5.....	Notts	Institute, Shakespeare-street.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, August 25, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. J. Traill Taylor presided.

The CHAIRMAN exhibited the results of his experiments to obtain good negatives upon plates which ordinarily gave fog, as described at the previous meeting; he maintained that similarly clean results could not be obtained by ammonia development.

Mr. A. L. HENDERSON thought that it would be fairer to let him have one of the plates to see if he could not get an equally good printing negative by ammonia development. A sulphite developer suited a slow plate.

Mr. B. WOLLASTON believed that equally good negatives could not be obtained with ammonia.

Mr. A. COWAN thought it to be possible to obtain as good results with ammonia and pyrogallol.

The Chairman exhibited a photograph taken by Mr. Joseph Gray of a flash of lightning.

Mr. COWAN hoped that there was no joke about it, for it looked like a print of a piece of cotton laid upon paper.

Mr. J. BARKER said that there was no halation such as usual with lightning flashes.

Mr. A. HADDON had never seen a flash of electricity which turned upon itself so as to form loops, as in the print.

Mr. WOLLASTON thought it impossible for a flash to so turn upon itself.

Mr. HENDERSON supposed it might be a flash of greased lightning. He was willing to write to Mr. Gray for full details of the conditions under which it was photographed.

The Chairman exhibited a pretty good view photograph by Mr. Dunmore, taken without lens, camera, or stand. A hole had been pricked in a piece of tinfoil and fixed upon the top of his felt hat, the plate had been placed in the hat some distance from the crown, and the light had been kept from the back by stuffing in a handkerchief; the exposure had been of half an hour's duration; it was a fair photograph, quite sharp.

Mr. H. M. Smith exhibited Eastman's new light-weighting roller slide, as described by him at the previous meeting.

Mr. WOLLASTON said that it had a clever frictional arrangement to keep the paper tight.

Mr. Henderson exhibited Bracher's automatic still for distilling water over an ordinary household fire.

The CHAIRMAN stated that Mr. John Stuart, of Glasgow, was selling large photographs of a group taken at the Convention at a cheap rate to members of the photographic craft.

Mr. Atkinson exhibited some very good quarter-plate landscape views he had taken in the Killarney district.

The CHAIRMAN remarked that a German periodical had published a good photograph of a meeting of the German Photographic Society; the members were indulging in lager beer, and had the appearance of being jolly good fellows.

Messrs. A. P. Higgins and E. G. Dornbusch were elected members of the Association.

The meeting was then made special to deal with matters relating to the new rules, after which it adjourned for a week.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting was held on Thursday, August 25, at the Royal Institution.—The President, Mr. George H. Rutter, in the chair.

The minutes of the last meeting were read and confirmed.

Mr. RUTTER reported on the Southport excursion in the absence of Mr. B. Boothroyd. It appeared that only five members took part.

The HON. SECRETARY read report of the Ingleton excursion on Bank Holiday. Seven members and five friends, carrying in all nine cameras, were present; seventy exposures were made, of which thirty were Ilford plates, twenty-four Eastman films, and sixteen Edwards's plates.

Mr. A. W. BEER reported that the Tongue and Lilleshall excursion did not come off, as only two members gave in their names beforehand.

The HON. SECRETARY read report of the Frodsham excursion, in which only three participated, who made seventeen exposures, the weather being dull.

Mr. E. ROBERTS gave an account of the Obernetter's emulsion paper, on which he showed several prints; he also exhibited Newman's patent shutter.

The Hon. Secretary showed prints on Rivot's self-toned paper, also a series of prints from the Ingleton excursion.

Work was also exhibited by Messrs Sayce and Day.

Mr. W. A. WATTS opened the discussion on Mr. Beer's paper on slow development. He quite agreed with slow and tentative development, having practised it in his own work, but he had not previously tried the developer recommended by Mr. Beer, namely, the American Standard Developer, which, he said, many persons confused with Beach's. He worked Eastman paper exclusively, employing first the Eastman soda formula; not liking the working of that, he tried carbonate of potash, using it proportionally to the carbonate of soda. Although he had read of the American Standard or ferrocyanide developer, he had not thought it could surpass the potash one until he saw Mr. Beer's negatives; but, being much struck with their beauty, both for gradation of density and freedom from stain, he had made up some ferrocyanide developer, and tried it with very great satisfaction and success. He no longer needed to use clearing solution, as the films were quite free from stain, and he recommended those present who had not yet given this developer a trial to do so.

Mr. BEER had heard that some persons found the American Standard Developer to stain; he thought that when that was the case it might arise from the omission of the sulphite of soda.

Mr. RUTTER had thought that the ferrocyanide developer was not suited for Eastman films, and he pointed out that in the Eastman instructions for stripping films they direct that not more than six of sulphite of soda must be used to one of pyro, whereas Mr. Beer's formula gives four ounces of a ten per cent. solution, or one hundred and ninety-two grains of sulphite of soda to six grains of pyro.

Mr. B. J. SAYCE said that if a plate was duly exposed there was no difficulty in development, but if under or over exposed then came the difficulty, and that was intensified by the fact that we work by seconds and fractions of seconds where the older processes took minutes; if, for instance, the correct exposure was one-one-hundredth of a second and we gave only one-two-hundredth that was a large amount to pull up, but it might be done by slow development. He generally gave slow development—half an hour on an average, but one of the interior of Speke Hall took an hour. As an encouragement for patience in slow development, he had given, when using the shortest exposure on collodion-albumen plates, as much as a week in development.

Mr. J. H. DAY said as American development had many advocates he would speak in favour of the older Swan method coupled with slow development. He used one drachm of ammonia and one drachm of bromide of potassium in ten ounces of water, dissolving dry pyro in an equal quantity of water, using ounce for ounce of solution, but beginning with only one-third of the quantity of ammonia solution and adding the remainder as development progressed.

Mr. Sayce showed a new note-book that he had prepared specially for his own use, but which any printer or publisher was at liberty to copy. It is intended to meet the wants of those who use the roller slide, and contains a column for the *winder's initials* to be added as soon as wound off, thus obviating double exposures.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of the above Society was held in the Technical Schools, Bridge-street, on Thursday, the 25th ultimo.—Mr. G. A. Thomason in the chair. Forty-nine members present.

The minutes of the last meeting were read and confirmed.

The following gentlemen were nominated for election:—Messrs. Greening, Copnall, Shilton, and Venour.

The HON. SECRETARY (Mr. J. H. Pickard) read a letter from Mr. B. Karleese, relinquishing the co-Secretaryship on account of pressure of business and ill-health.

A number of members having spoken with regret of the loss to the Society of the help of Mr. Karleese, it was resolved unanimously that the best thanks of the Society be given to him for his past valuable services, and hoped that he would soon be able again to render his great help and assistance.

Mr. W. Rooke was elected to the vacant co-Secretaryship.

A number of photographs were shown, taken during the holidays by Messrs. Harold Baker, Leeson, Godfrey Thomason, Tylar, and J. H. Pickard.

Mr. S. DELICATE read an instructive paper on *Outdoor Photography*. In the course of his remarks he said the paper was intended for beginners and members who had recently joined the Society more than for the older members. He divided it under three heads—The Lens, The View, and The Development, and pointed out that the best lens for general outdoor work was one of rapid rectilinear or rapid symmetrical type, these being the proper lenses for architectural subjects. But in some cases, as landscape with only such buildings as cottages, a single view lens would often give brighter negatives than the former; and in some views it is necessary to employ a wide-angle lens to enable the photographer to get in all the view he requires. The ratio of the stops was next explained, and it was shown how the stops may be measured and numbered. Under the second head—The View—the speaker remarked that every photograph ought to be so taken that it will have a striking and also a pleasing effect at first sight. Several kinds of composition were then explained, light, and shade, and contrast, were dealt with, and directions were given as guides to correct exposure. In the last part it was considered how best to develop a plate after it had been exposed. He kept all his chemicals in separate bottles, and by this means was able to modify his developer to suit any plates or any exposure; then explained how to treat different exposures. For an over exposed plate, mix a developer with a good supply of pyro, a large quantity of bromide, and a very small quantity of alkali; but for an under exposed plate the developer would contain very little pyro, little bromide, and a large proportion of alkali, to commence with. As soon as the details were well out add more pyro and bromide to obtain density.

Concluding by saying that an amateur having mastered the use of his lenses, how to place a view on the ground-glass in an artistic manner, and develop the negatives properly, had secured a good grasp of what is necessary for outdoor photography.

A discussion followed, which brought forth a challenge from Mr. Dennison that no good landscape could be taken on an Hford plate, which provoked considerable remarks and comments. The challenge was taken up by Mr. Welford, who undertook to disprove the same at the next meeting.

Mr. TYLAR read his report of the excursion to Tintern and Lymonds Yat on August 1 last. He said, leaving Birmingham by Great Western Railway at five a.m., we arrived at Lymonds Yat at fifteen minutes past eight, having had a long ride through magnificent scenery. A considerable number of views were taken here, one not having far to wander to obtain good views. Taking the train again, we proceeded to Tintern, *via* Monmouth. On arriving we rode to the Abbey by brake. The ancient ruins were admirably suited for pictorial making, both exterior and interiors giving numerous good effects of light and shadow. It was intended to have gone on to Chepstow, but the daylight waning, the remainder of the time was spent in strolling about till the departure of our train, which arrived back into town at fifteen minutes past eleven p.m., having had a long day's outing, but a very enjoyable one. One hundred and thirteen plates were exposed, namely, eighty-three Hford, six Abney, and twenty-four Eastman stripping films.

Mr. WELFORD gave a short paper on the *Wants of Amateurs*, and exhibited a detective camera (German) with which he had had considerable success; and the meeting terminated with the announcement of the paper for September 22 namely, *Stripping Films*, by E. H. Jaques.

Correspondence.

Correspondents should never write on both sides of the paper.

NOTES ON DAGUERRE FROM A MANUSCRIPT WRITTEN BY M. MENTHENNE, EX MAIRE DE BRY-SUR-MARNE, A PERSONAL FRIEND OF THE INVENTOR OF PHOTOGRAPHY, KINDLY COMMUNICATED TO PROFESSOR STEBBING BY M. GLAISE.

LOUIS JACQUES MAUDÉ DAGUERRE was born at Cormeilles en Parisis, Seine et Oise, the 18th of December, 1787. His father, a clerk in the Financial Department of the State, desiring to give his son an honourable profession, placed him, when yet young, under an architect. The youth manifested very early a decided taste for painting. His parents used their influence to divert him from this art, but in vain; his resolution to be a painter was immovable. His father, yielding at last to his great desire, apprenticed him to Degotis, decorator of the Opera. It was not long ere the young Daguerre made rapid progress in the art he had chosen. Important decorative work was confided to him, and he soon gained the reputation of being a talented artist.

He received an order for a theatrical scene for the l'Ambigu-Comique, and made a complete revolution in this style of decoration. His paintings for that theatre are still cited as *chefs-d'œuvre*—*The Dream in the Chapel of the Castle of Glenhorn*, *De la forêt de Senart*, &c. He then executed, in collaboration with M. Ciciéri, the decorations of the wonderful lamp for the great Opera; the magical effect of his rotating sun was remarkable. He assisted Pierre Prevost in the execution of his panoramas of Rome, Naples, London, &c. About this time he associated himself with the painter Bouton, for a moment a rival of Horace Vernet, in view of a panoramic establishment, in which light was made to act in order to give mobility to the effects as well as a charm to the coloration. This establishment was opened to the public on the 11th of July, 1822. Here he offered to the astonished view of the spectators most admirably painted pictures, which, by the different effects of light, were made to pass from daylight to night, and from one scene to another. Renown spoke of a valley in Switzerland: Holyrood Chapel—this was so wonderful as regards painting, as well as scenic effect, that the Government decorated him with the Cross of the Légion d'Honneur (1824). *The Abbey of Roslin in a Fog*—which transformed itself into a snowstorm, *The Fire of Edinburgh*, *The Deluge*, *A View of Paris taken from Montmartre*, *The Tomb of Napoleon at St. Helena*, *The Mont Blanc*, *The Black Forest*, *The Midnight Mass at St. Etienne du Mont*, *The Temple of Solomon*—this was his last production for his diorama (1839). This exhibition gained for its author universal renown; foreigners came from far in order to witness such a novel and wonderful sight.

Master of his art, Daguerre produced by his perspective the most complete illusion—darkness to light, as well as all the atmospheric variations, were scrupulously represented. All at once the spectators were carried, as it were, into the centre of an immense cathedral—the arched roof, the immense pillars, and the coloured glass windows admirably portrayed—perspective had created space with striking reality. Then the admiring sightseers were shown a landscape lighted up by the silver beams of the moon, a castle hidden in the shade of a grove of trees, the heavens beautifully decorated with silver and golden tipped clouds. As a type of these changing panoramas must be cited the famous *Midnight Mass*, seen at first by daylight, then during the night service. This change was obtained upon the same picture, and without removing it in the least.

The 3rd of March, 1839, a fire devoured these *chefs-d'œuvre*, and many others having a great artistic renown and value. This was, indeed, a

misfortune. From that time up to the present day no establishment of the kind has been got up.

Through this inauspicious event the fortune of Daguerre was very much curtailed. He continued, nevertheless, to occupy himself with the different effects to be obtained by light. Since 1834 he had been seeking to fix the image obtained in the camera obscura. This idea had been ridiculed by all those he had spoken to on that subject, with the exception of the eminent chemist, J. B. Dumas, *l'illustre savant de l'Académie Française*, who gave him every encouragement to continue, and prognosticated his future success. In fact, as a recompense for the loss he had sustained by his fire, towards the end of April, 1839, he discovered the means to fix the reproduction of nature by means of light.

Henceforth an immense fortune appeared to lay beneath his grasp. Brilliant offers were made to him by foreigners for the purchase of his secret. England, which is never behindhand, offered him 10,000*l.* sterling and an annuity of 1000*l.* Prussia and Russia made him most brilliant offers. The United States offered to give him whatever he might demand. But Daguerre was resolved to give the honour of his discovery to his native country. The statesmen of France voted him unanimously a national reward in the form of a pension for life.

By a deed executed before a notary, signed June 15, 1839, he took the solemn engagement to reveal the process he had discovered to obtain proofs by the aid of light, as well as to publish the means he employed to obtain such admirable effects in his dioramas. For this abandonment of his invention he was to receive from the State the humble pension of 240*l.* per annum. The Government decorated him *Officier de la Légion d'Honneur*; the King of Prussia sent him the Order of Merit; the Emperor of Russia sent him a handsome present; the Universities of Edinburgh, Vienna, Munich, and New York sent him the diploma of honorary member of their respective colleges.

Daguerre, desiring to rest a little from his labours, purchased a charming villa in the hamlet of Bry-sur-Marne. He occupied himself in embellishing his dwelling, and there he spent, with his worthy and respectable wife* and his niece (not having any children of their own) the happiest portion of his life. At the same time he did not neglect his taste for scientific subjects. Probably to please the priest he took it into his head to decorate the humble village church. Behind the high altar he prepared a canvas frame nearly five yards square, lighted from above; upon this he painted one of his very effective pictures—the only one left which can give the visitor an idea of what his Diorama was before its destruction.

The decoration represents a Gothic edifice from the *jubé* to the choir. This changes totally the aspect of the little village church, giving it the noble and majestic appearance of a cathedral. The visitor remains in wonder and admiration, looking at the numerous details of that holy scene. The curves of the archwork are so exquisitely rendered that the air appears to float among the pillars and the breath of prayer whispers among the arched buttresses. Spiders' webs can be seen hanging from the acanthus of the chapiters. In the foreground, Christ upon His cross appears about to descend. On the other side a wax taper is represented as being just extinguished, wafting its slightly curled and transparent smoke towards the skies, leaving the wick glowing red. Many other details could be mentioned which when touched are but optical illusions! By this last piece of work Daguerre appears to have left a pledge of his friendship and high esteem for the inhabitants of Bry-sur-Marne.

During his retreat he occupied himself with his favourite studies. He became a member of the Free Society of Fine Arts, established in 1830, and assisted very regularly at their meetings. It appears he sought diligently to obtain instantaneous results for his photography. In the year 1844, at the meeting of the Free Society of Fine Arts held on January 30, he communicated his hopes that he had found a new chemical of which the sensitiveness was so instantaneous that he intended to make the portrait of a horse at full gallop. "The effect is so prompt," said he, "that I can only compare its rapidity to the velocity of the electric spark." Daguerre was very particular and difficult as to the perfection and easy application of his inventions. Perhaps he did not attain the success he desired as to rapidity, for at his death nothing could be found relating to this subject, which appears strange and unaccountable.

He endeavoured to bring designs in pastel to perfection by seeking a manner to fix the colour upon its support so as to away with the protecting glass which was necessary at that time. It appears he met with many difficulties in order to preserve the velvety appearance so precious in that kind of drawing.

At the moment when death knocked at his door he was occupied with a new process of monochrome painting on glass to be seen by reflection. The glass replaced the best varnish, and gave a highly glazed appearance to the finished picture. The specimens he left are painted with black paint, very vigorous indeed in tone. The half tones are obtained by means of the semi-transparency of the coating, this coating being more or less thick according to the taste of the artist. A coating of white to finish up gives depth of shadow. Several landscapes executed by this process were terminated, and one nearly finished was found upon the easel. As to the mode of production and preparation it can only be surmised, as nothing was left by him on the subject.

Although busy in study and science, he was not against rendering service to the inhabitants of the village he had chosen for his retreat.

* Louisa Arrowsmith, an English lady.

Advice and help was not withheld from those who had chosen him to represent them on the Municipal Council.

He received many visits from strangers and foreigners; photographers and artists came even from America, among them Messrs. Meades, who took the portrait of the master they came to honour with the intention of reproducing it on the other side of the ocean, to make the features of the celebrated artist known to their countrymen.

He was very friendly with *Mlle. de Rigny*, niece of the Baron Louis de Rigny, the great banker. This lady was owner of the greater part of the village, very learned, at the same time advanced in science. Daguerre found great pleasure in her society.

In 1848, during the great Revolution, the inhabitants of Bry were in the greatest distress. He occupied them in the park of *Mlle. de Rigny* in making a miniature representation of Switzerland. Mountains, rocks, old castles, ruins, lakes, bridges, &c., all were represented on a large scale. A double object was here obtained—an artistic work was accomplished, and the workpeople were prevented from frequenting the national workshops, where bad doctrines were inculcated rather than honest work counselled.

Daguerre died suddenly on July 10, 1851, in the prime of life. A few days before his death he took part in the work of a commission *des Beaux Arts*, and nothing could prognosticate that his end was near.

His loss was universally regretted. When the sad news reached the New World the photographers there sent addresses to his widow, expressing the deepest regret for her bereavement. In order to show their admiration and acknowledgments to Daguerre, they were mourning during eight days, in sign of sorrow for his loss. A sum of 2000*l.* was collected to build a monument to his memory at New York, so as to show to all nations that the American photographers admired and appreciated the invention of Daguerre.

The mortal remains of this great artist repose in the cemetery of Bry-sur-Marne, where a monument has been erected to his memory by the *Société Libre des Beaux Arts* in the midst of those he loved, surrounded by his friends, which he considered as belonging to his own family.

M. Glaise writes me to-day, "The monument is in stone, two and a half yards high. In the centre is the bust of Daguerre. The inscription is:—

A.
DAGUERRE,
La Société Libre des Beaux Arts.
MDCCCLII.

"On the back of the stone is the date of his birth and death, also that of his wife, who survived him six years."

DUBLIN PHOTOGRAPHIC EXHIBITION.

To the EDITORS.

GENTLEMEN,—May I, through your columns, remind intending exhibitors that the time for sending in is now approaching, the 15th October being the last day on which pictures, &c., can be admitted? Prospectuses, entry forms, &c., can be obtained from the undersigned.—I am, yours, &c.,
GREENWOOD PRIN, Hon. Sec. Exhibition Committee.

Monkstown, Co. Dublin.

P.S.—It would much facilitate if applicants would kindly say how many labels they desire.

THE AMERICAN STANDARD DEVELOPER.

To the EDITORS.

GENTLEMEN,—Your effervescent and sparkling contributor "Monitor," scarcely appears to have taken in Mr. Beer's meaning in his valuable paper on "slow development" read before the Liverpool Amateur Photographic Association, at least, so I judge from the tenor of his remarks. The absolute amount of potash solution to be employed depends, of course, very much upon the amount of exposure the plate has received, and Mr. Beer doubtless gives a very full exposure, so needing a weaker developer to finish with than perhaps many others might do, or than "Monitor" himself would do were he to condescend to try the "American Standard Developer," which, from the tenor of his "Echocs," I conclude he has not yet done. In referring to Mr. Beer's advice to begin with one drachm only (one-eighth normal strength), it must be borne in mind that this is only tentative—should there be much over exposure no harm will have been done, whereas if development does not begin it is easy to add more potash solution.

May I venture further to reply to "Monitor's" question (I don't know to whom addressed), "What constitutes the American Standard Developer, and who appointed it standard?" On page 275 of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1887, he will find given the *Standard Developer of the New York Amateur Society*. It was recommended as a standard developer by a Committee of the Society in question, specially appointed to consider the subject of dry plates and developers. I regret I cannot at this moment lay hands on their report, but it has appeared in the photographic journals, and therefore has as much claim to be considered standard as, for instance, the Standard System of Stops of the Photographic Society of Great Britain.—I am, yours, &c.,

THE HON. SEC. LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

PHOTOGRAPHY WITHOUT CAMERA OR LENS.

To the EDITORS.

GENTLEMEN,—Enclosed please find a photograph taken without any of the usual apparatus—no lens, no camera, and no stand. It was made in this way. A bit of tinfoil was gummed over the ventilator of my felt hat, in which a small hole was made with a needle, a plate was stuck by the corner inside the hat, a large red pocket-handkerchief stuffed in behind it, over which I placed my coat. The hat and its contents were then set level as I could judge on a coil of hose that happened to be lying handy, and exposed to the view for half an hour, that was all. The result you will see is a fair photograph, but not quite sharp. Perhaps a smaller hole and longer exposure might improve matters.—I am, yours, &c.,

Beacon Hill, N., August 25, 1887.

EDWARD DUNMORE.

FIFTY SITTINGS FOR A PORTRAIT.

To the EDITORS.

GENTLEMEN,—I have been scanning with interest the correspondence in your columns about the use and uselessness of photographs to artist-painters, and as I have had some experience in the matter, both practically and theoretically, I may be allowed to premise that the parties on both sides of the question are right individually.

That photography can effect an immense saving of time to the sitters getting their portraits painted, no matter by whom, but that the art of the picture is proportionably enhanced is problematical, to say the least of it.

Then, with many artists (some of whom are under the suspicion of mercenary-mindedness) of no small ability, the use of photographs not only aids them greatly with their work, but it enables them to send out far more likenesses than they could possibly do if working from the sitters alone. Some trained artists of great popularity, both in Scotland and England, to my knowledge, neither scruple to use or tell you they use photographs whenever suitable ones present themselves. Sometimes even the negative of a favourite portrait is borrowed for the purpose of throwing the image on the canvas and outlining it with the pencil.

There is a class of artists, however, who cannot use photographs, and, curiously enough, those whose sense is strong in form would think that said class, from their weak draughtsmanship, would be none the worse of a lesson from the accurate forms of photography; but no, such artists are in pursuit of other truths, so few of them concern themselves about severe form. Firm, accurate form with them is mere still life. Loose, shifting form lives or moves. So to the artist striving to reach the higher ranges of nature, the spirit of things carries him captive, and consequently he is apt to spurn matter-of-fact photography, yet knowing and feeling all the time that photographic truth is precious, but that it is nevertheless far down the scale of truth.

But beside all this, there are artists of the highest susceptibilities to the subtle power of colour, who for the life of them could not draw accurately enough, as a rule, to make a striking likeness, and yet these men will be the last to use photographs; and why? Simply because they, too, are spellbound by Nature while she is in the mood of displaying her beauty or her mysteriousness—a mysteriousness that none but an artist can know, so much has colour to do with such appearances.

Seeing, then, that the practice of art is so much a matter of idiosyncrasy, the solution of the present question is obvious, and accordingly it may be asserted that the painter-artist, whether weak or strong in form, if of the peculiar cast of mind indicated, has no need of—indeed, cannot use—photographs. Such minds will grapple with the higher difficulties of art, that they may render in their work the higher real, the true ideal, in nature, while those who can use photographs, although to great advantage at times, must, as a rule, be content with a lower excellence in their work, however much they may strive to also reach the higher truths. How could it be otherwise? Can a photograph speak like Nature herself? No, undoubtedly no. Why, when a painter is under the influence of natural appearances he has no control over himself. Nature is a tyrant at such moments, and will drive him to despair if he fails in his ability to render her teachings. Has any one felt the power of a photograph so strongly? If not, only one inference can be drawn.—I am, yours, &c.,

Edinburgh.

JOHN PATRICK.

To the EDITORS.

GENTLEMEN,—As my answer in last week's JOURNAL does not seem to have given complete satisfaction to "A Painter," I will try to give him what I think will prove such, if you will kindly allow me the space. In his last letter he states (without the least regard to facts, although I advised him to re-peruse the "par." in my original article) that I, speaking of Sir Joshua Reynolds and Sir Thomas Lawrence, "told us how many sittings they wanted to produce a portrait, and that nowadays, by the aid of photography, we have done with such troubles." As I suggested, this is not true, as may be found by reading my "par." on page 406 of the JOURNAL. If I had said such a thing I would have been laughed at, and deservedly—but I didn't. I simply stated that Sir Thomas Lawrence and Sir Joshua Reynolds "have repeatedly had as many as fifty sittings for a portrait," and so on; but although they had so many I can scarcely think they absolutely wanted them all. It was sufficient, however, for the purpose of my article to mention the fact of its being recorded that these celebrated artists had had that number of sittings.

A great grievance with "A Painter," too, seems to be that I should have thought it possible for such illustrious men to receive help from photography, or even dare to mention their names and photography in the same breath. Might I ask what he suggests by asking, "Now, to what comes the help Mr. R. Barrett advises us to obtain from photography?" This I can only answer by saying that if "A Painter" can honestly thus place himself in such company as Sir T. Lawrence and Sir J. Reynolds I might be disposed to say, "Don't look for such help."

"A Painter" was very unfortunate in last week's selections for quotation from my letter wherein he mentions Sir F. Leighton and Sir J. E. Millais, as he evidently did not see the little harmless joke therein. I think, however, the letter of Mr. Herbert S. Moberly—it is particularly worth noting that this gentleman is not an anonymous correspondent—in your last issue will furnish a better answer than any I can give, as I have not the honour of knowing either of these gentlemen except by their works. I may, however, draw attention to the fact that the acknowledgment of help is most complete, and also especially points out that the assistance of the photographs saved the absolute necessity of a considerable number of sittings. I feel extremely obliged for the testimony of Mr. H. S. Moberly, as it is a more than ordinarily valuable one. As a guide to colour those photographs would be useless, and therefore could only be a help to secure the outline and expression. I presume there is no one foolish enough to think that Sir F. Leighton needed such help; nevertheless he accepted it because circumstances dictated the advisability of such a course. No artist can possibly want the help of photography less for the sake of outline than Sir F. Leighton, as I think it is very generally conceded that probably no artist ever lived who had mastered all the details of the human form so completely.

"A Painter" finishes his letter with "The other remarks in Mr. R. Barrett's answer I consider as irrelevant, and do not care to reply to, and I think we have had now enough said about the question on both sides, so as to enable any impartial reader who cares for it to draw his own conclusion," &c. I fear I must disagree with him in this opinion, as I do in nearly every other that he has offered, although, I think, up to date the impartial readers are nearly all on my side. THE BRITISH JOURNAL OF PHOTOGRAPHY has a very large number of not only impartial readers, but close and attentive ones, and is read alike by artists as well as photographers; yet, strange to say, "A Painter" stands alone in taking exception to my remark as made in *Colouring as Applied to Photography*. The remarks in my answer which "A Painter" considers irrelevant, I maintain are not so, unless (which is possible) we have got different ideas as to the meaning of irrelevant. If "A Painter" did not wish to have the other portions of his second letter answered, he should have written across them, "Please take no notice of this—they are only passing remarks upon subjects of which I have but a slight knowledge." I would then have taken no notice of them. Besides, I do not expect a reply to what I wrote; what I did write was a reply to his remarks.

It is all very well to say that matter is irrelevant, but I beg to insist there was nothing of such a nature in my answer. If he refers to his letter, he will find I have only answered the points therein. It is evident that he does not hesitate to give strong opinions upon matters of which I feel sure he knows but little, judging by those given in his second letter to your JOURNAL. One should have good grounds beyond their own cramped opinion before taking to task any assertion authoritatively laid down. We are all liable at times to make mistakes, and I am always very grateful when any correspondent offers me advice, or differs from me in opinion, but I expect the same always to be backed up with something more of common sense and knowledge of the subject than I have succeeded in finding in the letters of "A Painter." I begin to think now that the matter was a joke, and that I should never have taken it up seriously, but treated it like your correspondent, Mr. Herbert S. Moberly, to whom I once more offer my thanks for his independent testimony. Apologising for trespassing so much upon your valuable space, and thanking you for the same—I am, yours, &c.,

REDMOND BARRETT.

To the EDITORS.

GENTLEMEN,—In your JOURNAL of the 19th ult. (I am sorry now to say it) I rushed rather hastily into print. Since then I have made it my business to make inquiries as to the connexion between artists and photographers, and am quite astonished at the amount of work done for the former by the latter. I have gone in for the matter, and had it thoroughly explained to me, and I cannot find how a work suffers, as a work of art, by the help derived from photography, when legitimately used. I would not thus trouble you, but as I took exception to your correspondent's (Mr. R. Barrett) theory, which I thought incorrect at the time, I feel I owe him an apology now I find he was right in what he said. It will be a lesson to me in future not to offer an opinion on what I don't thoroughly understand.—I am, yours, &c.,

AN ARTIST.

St. John's Wood.

A CORRECTION.

To the EDITORS.

GENTLEMEN,—I wish to call your attention to an error that has crept into your last report of the proceedings of the North London Photographic Society, at which I am made to say I "only used two stops, namely,

fr and fr." What I did say was, that "I thought two stops were sufficient for general work—No. 16 and No. 64 U. S."—which makes all the difference.—I am, yours, &c.,
EDWARD DUNMORE.
Beacon Hill, N., August 26, 1887.

Exchange Column.

- I will exchange a 12×10 rapid doublet lens by Burr for a half or whole-plate camera.—Address, C. BANYARD, Southwold, Suffolk.
- I will give a good Spanish mahogany stereoscopic camera, twin lenses, for half-plate instantograph.—Address, W. SAUNDERS, Dickleburgh, Soole.
- Will exchange magic lantern, three-inch condensers, for quarter-plate bellows camera and lens.—Address, HUGHES, Sunderland-terrace, Ulverston.
- Will exchange a magic lantern, fitted with solar lamp, four-inch condensers, and sixty slides, for a Lancaster's lens to cover 12×10.—Address, P. COSTA, Photographer, Southend-on-Sea.
- Wanted, pair of three-inch wide-angle symmetrical or rectilinear stereoscopic lenses in exchange for pair of longer focus or for cash.—Address, W. I. CHADWICK, Brooklands, Manchester.
- Changing box and dark slide by Ottwell, carries eighteen stereoscopic or quarter-plates; will exchange for half-plate view lens or for quarter-plate camera and lens.—Address, S. HALLON, Station-street, Lewes.
- Wanted, first-class half-plate camera (Middlemiss or McKellen preferred), three or more double slides, hot rolling press, ten-inch rolls; exchange, Rudge rotary tricycle.—Address, W. E. LEEK, 11, Tronmarket, Newcastle, Staffordshire.
- This year's *American Annual and Mosaics for fifteen months' Camera*; six-and-a-half-inch burnisher for quarter-plate lens; 18×12 white glass bath and dipper, cost 45s., for first-class retouching desk, graphoscope, or embossing press.—Address, C. C. VEVERS, Horsforth, Leeds.

Answers to Correspondents.

PHOTOGRAPH REGISTERED:—

- E. J. HOLMES, Post Office, Cranbrook.—Combination group of buildings and Masters of Queen Elizabeth's Grammar School, Cranbrook.
- R. A. A.—No.
- C. J. GRIMMITT.—Hardwich's *Manual*, published by Churchill, London.
- S. WELLS.—If Marion & Co. cannot supply what you require we do not know who can.
- K. W.—No doubt the paper will be permanent enough if the toning, fixing, and washing operations are properly performed.
- JAS. EDWARDS.—We have written to Mr. Crook respecting the Convention group taken at Edinburgh. He will doubtless reply in our next.
- RUS.—I. Without seeing the lens we cannot supply any data for making alterations.—2. There are mats and rugs sold specially for the purpose.—3. Thanks for suggestion.
- BARGO.—The stain is no doubt an iron one. If the alum and hydrochloric acid bath does not take it out we fear it is irremovable. Something must have been wrong otherwise the stain would not have been produced.
- T. W. HEPBURN (Grahamstown).—The reference to the lens being aplanatic must only be held as meaning that it will define sharply in the centre of the plate only with full aperture. To extend the sharpness over a large area it must be well stopped down.
- B. C. C. asks: "Can you tell me of any means of preventing prints cockling when drying?"—The best plan of avoiding the cockling is to dry the prints between blotting-paper or to place them where they will dry slowly. Rapid drying is almost sure to cause the pictures to cockle.
- THE MOUNT (Ackworth).—The stain is doubtless caused by the paper having been exposed to light with part of it covered up—that part which is white. It would appear that it was the back which was exposed, and not the front. It is true that the stain can be partly removed by indiarubber, but only by abrading and removing the surface of the paper itself.
- J. J. MACNAMARA.—It is difficult to account for the stains unless they are caused by the prints sticking together whilst they are in the fixing bath. If they were washed in an iron vessel which was oxidised, and they were allowed to rest on the bottom, this would cause a staining. The stain on the print sent is of a deeper colour than is usual with mere sulphuretting.
- J. S. STRANKS writes: "Will you kindly inform me, in your paper, where I can obtain a ready prepared emulsion for dry plates?"—So far as we are aware, gelatine emulsion is not an article of commerce. No doubt if our correspondent required it in large quantities any dry plate maker would make it to his order. Collodion emulsion, we believe, is still supplied commercially. He might write to Messrs. Rouch & Co. or to Messrs. Wratten & Wainwright.
- CORKONIAN writes: "Will you kindly inform me, in your 'Answers to Correspondents,' how to dull silver and gold plate so as to be able to get a good photograph of same, and at same time not in any way to injure the plate? I think I saw a formula for same in the JOURNAL about five or six years ago, but am unable to find it now."—There are several different plans of producing a dull surface on plate. One is this:—After the subject has been arranged and focussed, and the plate is ready for exposure, a piece of ice is put into the vessels; this will reduce the temperature of the metal to such an extent as to cause the moisture in the atmosphere to condense on the surface and so dull it. Another plan is to dab over the surface with a piece of putty; this will destroy the gloss. After the photograph has been taken the putty can be brushed off with whiting.

C.—The design for your suggested camera appears to be very good for the purpose you require, while it is very simple. Any camera makers would construct you one. The lens you name, or one of a similar type, would be about the best you could take if you only take one. The shutter mentioned is also very good, but, as you say, cumbersome; you must not, however, expect to obtain every advantage without some slight drawback. A simple form of drop shutter would be more portable if slightly less efficient.

SILVER IODIDE.—1. You had better treat the bath the same as recommended to "W. H." in reply to query No. 1.—2. Better get price lists from makers of second or third-rate reputé.—3. Unless we saw the negative we could not give a decided opinion. From your description the markings are somewhat different from those usually arising from imperfect washing between the intensifying operations. It would rather seem that the long continued washing had disturbed the gelatine film, and this might possibly be the case if the water had been unusually warm.

CRAYON inquires: "Would you kindly inform me if there is any work published on 'Facial Anatomy,' and if not, what is the best mode of studying it for retouching?"—We have placed this query in the hands of Mr. Redmond Barrett, who replies: "I have never come across such a work as 'Crayon' seems to require. There have been many works upon anatomy, which naturally includes the face, such as those by Fau, Flaxman (a standard work), Marshall, and Tinney, &c. As, however, he has everything in the negative at starting, and there is rarely a necessity to place the muscles but simply to modify the severity of their expression, I would advise the perusal of the articles which appeared in the JOURNAL some little time back under the heading of *The Art of Retouching*. I should think they would prove sufficient for his purpose. If not, however, I would advise taking a few lessons upon this special branch."

W. H. inquires: "1. How must I proceed to make a negative bath into a silver printing bath?—2. What strength ought a silver printing bath to be? and how long should paper float to yield vigorous prints?—3. Should printing bath be acid or alkaline?—4. What is the cause of the toning bath (acetate of soda) turning a magenta and then a deep purple colour? and what would remedy it?"—In reply: 1. If the bath has been but little used it will simply require making up to the proper strength; if it have been largely used proceed as follows, to get rid of the iodide:—To each pint of the solution add about six or eight grains of citric acid dissolved in water; next add liquor ammonia till the blue colour of reddened litmus paper is completely restored; now expose to a strong light for a day or two, then filter, and make the solution slightly acid with nitric acid, and then strengthen.—2. This will depend upon the amount of chloride in the paper; about fifty grains to the ounce is sufficient for most commercial paper. Two to three minutes will suffice.—3. Very faintly acid.—4. The discolouration of the bath arises from a reduction of the gold, owing to some extraneous cause, say, putting the solution in a dirty vessel, or contamination with hyposulphite of soda, &c. Keeping the solution in a strong light will also cause the gold to become reduced.

RECEIVED.—Mawson & Swan's Pocket Diaries for September and October.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, September 7, 1887, will be on *Dark Room Arrangements*. Saturday outing at Carshalton. Train from Victoria near two o'clock.

INDECENT PHOTOGRAPHS.—A hawker named Marcus Levy was charged in the City Police Court of Edinburgh with having offered for sale and exposed to view in his barrow at the Mound fourteen photographs of an indecent and obscene description. He pleaded not guilty. Mr. William M'Donald, agent, who defended, argued that, with the exception of four, the photographs were classical, such as would be seen in almost any print shop in the city. He produced in court two photographs purchased in two respectable shops on Thursday, and contended that they were worse than those seized by the police as indecent. When a man was charged with an offence of this kind it should be fairly shown that he had really committed an offence—that he stood out prominently from others who dealt in the same things as one who had grossly offended. He asked the Bailie to remember the nature of the figures exhibited in statue galleries. Bailie Walcott said that, altogether apart from the different positions in which the photographs were found on the barrow—some of them being loose, so that any one could see them, and others being in a box, to be shown if required—they naturally divided themselves into two classes. Some of them were nude figures—not all equally good, not all equally bad. Many of the photographs were certainly representations of easily recognised works of art, and to condemn them would involve the condemnation of the works of art themselves. He must say that there were some of them, however, he did not think could have come from the chisel of men who were moved by the highest motive or the highest principles of art; but he intended to put them aside—he did not object to them on the ground that they were nude. Four of them were essentially bad—things that no high-souled artist would produce, and things that no man who had the love of his fellow-creatures at heart would exhibit for sale, or purchase if offered for sale. Especially on the ground of these four photographs he found the charge proven, and fined Levy 1*l*, the alternative being five days in prison.

MOUNTING PHOTOGRAPHS IN OPTICAL CONTACT WITH GLASS.

From what has, from time to time, appeared in our columns in connexion with this subject, one might have surmised that it would now be fully understood. Such, however, does not appear to be the case with many, if we may judge from the correspondence we are continually receiving. Now the cementing of a print in optical contact with a glass plate is really a very simple thing, all that is necessary being to prevent air bubbles from getting imprisoned between the glass and the paper, and to expel all the superfluous adhesive medium, whatever that may be. Such is the process in the abstract.

With reference to the adhesive material, almost any may be employed—such as starch, gum, dextrine, or gelatine. On the whole, perhaps, the last named is the best and most convenient medium to use, and, for this reason, it is the one almost universally adopted. From correspondence received, we are quite aware that many have failed with gelatine, but, in most instances, we have been able to trace the trouble to one or other of a very few causes. These are usually the employment of gelatine of an unsuitable character, or using the solution too strong, or not warm enough, or, perhaps, from not expelling sufficient of the mountant after the print is brought into contact with the glass.

Let us now consider these little points in detail. First, the character of the gelatine. Some have assumed that a gelatine devoid of colour is an essential, otherwise the whites of the picture will be degraded. This is a fallacy, because, if the manipulations be properly carried out, the intervening film will be so attenuated that it will have no influence whatever on the print—unless, indeed, the very darkest glue were used, and even then it is somewhat doubtful. Most colourless gelatines, such, for example, as the foreign ones used for dry plates, have a rapid setting property, which is a very bad one for our present purpose, inasmuch as it increases the difficulties of manipulation considerably. Moreover, most of the foreign gelatines contain a certain amount of free acid, which may, with time, act injuriously on the mounted picture. A slow-setting gelatine—that is, one which might be considered, from a manufacturer's point of view, as of an inferior quality—should be chosen, even at the risk of its being somewhat coloured. With reference to the strength of the solution, many have met with trouble through using it stronger than necessary. A comparatively weak solution is far more adhesive than many would imagine. Regarding the temperature, if it be too low a difficulty will be experienced in removing the superfluous gelatine. The same remark will, of course, apply if the glass plate itself

is not made as warm as the solution. With these comments a novice should experience no difficulty in carrying out the following instructions without risk of failure.

The glass plates, which should be of good quality, and free from scratches and air bubbles, must be thoroughly cleaned, and the prints trimmed to a trifle less than the size of the glasses beforehand. Now four ounces of gelatine—that known as Nelson's No 2 Soluble is very suitable and nearly free from colour—are soaked and afterwards dissolved in a quart of water. The solution is then strained through fine muslin into a warm dish placed in a water bath over a small gas flame to keep up the temperature. The most convenient arrangement is to have a couple of enamelled iron dishes—such as those used by platinotype printers, one standing within the other—the outer containing the hot water and the inner the gelatine. The temperature should be maintained at 110° to 115° Fahr. Before commencing the mounting, the trimmed prints should be soaked in cold water, and then placed between blotting-paper to remove the excess. The glass plates should be made somewhat warmer than the gelatine before the fire, or by allowing them to remain for a time in tolerably hot water. When the latter plan is adopted—and it is the best, as by it dust is avoided—a squeegee must be passed over the plate, back and front, to remove the water, and thus prevent the gelatine becoming diluted.

A warmed glass is now immersed in the gelatine, together with a print, and allowed to remain for a short time for the solution to soak well into the paper. The two are then brought into contact and carefully removed, so as to avoid the formation of air bubbles. Then, with a soft rubber squeegee applied with some pressure to the back of the print, the superfluous gelatine is expelled as completely as possible. The plate is then placed aside to dry spontaneously. The most efficient method of using the squeegee is to commence the first stroke about two-thirds from the end of the plate, carrying it firmly forward to the other end. The second stroke should then be made in the reverse direction, but under similar conditions. By this means, should any air accidentally get between the paper and the glass, it will be effectually forced out. The tool can then be used with considerable force crosswise. Before the damped print is placed in the gelatine it should be dusted over with a soft handkerchief to remove any adherent fibres from the blotting-paper.

It is a good plan, after the prints have been squeegeed down, to pass the squeegee over the face of the glass, in order to remove the gelatine from that, so that there will be less to clean off after the picture is dry. Or the wet gelatine may be wiped off with a sponge moistened with warm water.

If a more brittle sample of gelatine than that recommended be used, or the mounted prints are likely to be subjected to an abnormal amount of dry heat, a very minute trace of glycerine may be mixed with the gelatine, but this will rarely be necessary.

NON-CHEMICAL FOG.

THAT the proportion of foggy negatives out of a given number produced is, nowadays, far larger than was the case when wet-plate pictures formed the staple product of the dark room will, we apprehend, be denied by no photographer of experience. Whatever faults a negative might have possessed in those times, that of fogginess was the least common; for, whenever it was noticed that the chemicals had arrived at such a condition as to cause foggy pictures to be obtained, it was at once assumed that something was wrong, and a remedy sooner or later was generally found: we may say it was always tried for. But for a long while after the introduction of gelatine plates, a greater or less amount of fog grew to be looked upon as, if not a normal accompaniment of the process, at any rate a condition about which no trouble need be felt. The more so was this the case when of the many different varieties of fog it was found that some did not seem to injure the appearance of the finished print to any important, or, sometimes, even perceptible extent. There is far less tendency to fog in the plates which are now being sent out by the various makers; but while it is easy enough, even yet, to make foggy negatives with the best of plates, there are few expert workers who do not find fog presenting itself in one or other of the many batches of plates they buy in the course of a year.

This being the case, it is evident that the less experienced hand may come across instances of fog which he has no power of designating beyond suggesting that it is the plate that is at fault. A dozen years ago it would have been just the opposite; his first idea then would have been to examine his apparatus and his surroundings. It is therefore reasonable to suppose that there are many foggy negatives made by those whose only experience is dry-plate work, in which the defect is owing to causes other than chemical: lately, very many instances have been brought under our notice that have verified this supposition, and it may be of advantage here to discuss them. Our readers need not take alarm, and think that we are about to resuscitate any old controversies; there are plenty of indisputable facts without introducing polemics. Dark-room work strongly reminds us of the old saying, "What is one man's food is another's poison;" for, in regard to a question of illumination, a light that is safe to a plate in one position would ruin it when differently situated.

The lighting of a dark room is almost entirely a matter of degree, and when one person copies the exact colour of the light screen in a friend's laboratory, where are produced negatives of perfect brilliancy, he may quite easily go wrong, and obtain only foggy pictures unless the other conditions go hand in hand with the original. If he should be so unlucky, it will, in all probability, be long before he finds out the real cause. A certain professional photographer of some standing had many of his negatives slightly fogged through no other cause than the lighting arrangements of his dark room, although this subject was one he had experimented with to a considerable extent previously to his selection of a colour screen, and the mode and place of fixing it. It was a pure accident that led to his discovery of the extent to which his screens were defective.

On one occasion he had a negative of a particularly interesting subject which he was anxious to get through without one moment's loss of time. He made his exposure on a plate backed with coloured collodion, and, as this was of a very tenacious sort, he did not wait to remove it before development, but placed the collodionised plate at once in the solution. A long development was required, and many times during its course he held the plate up to the coloured window to see how the picture was progressing, and to facilitate his examination he rubbed away the coloured collodion from just behind the face. When the picture came to be closely examined after fixation he was dismayed to find a distinct, though slight, fog upon the face. A rigid examination was made, and the fact was clearly shown that the plate in its various examinations had, in the aggregate, received sufficient light to cause fog, though exposure at the ordinary distance during prolonged development caused no fog. Hence in his everyday work some plates were injured and others not, according to the frequency with which they had been examined. For the future this gentleman changed his screen, or, rather, he added another thickness of yellower glass, and this sufficed to prevent danger under anything approaching to average conditions.

Another professional photographer of our acquaintance, also in a large way of business, built himself a new dark room, glazing it with glass exactly similar to that made use of in his old room, with the one exception that there was a much greater area of it in the new place. Here, again, fog trouble arose, and it was not discovered for some little time that the cause was the different conditions under which the light screen hitherto found to be perfectly safe had been used. Now these two instances occurred with professional photographers expert at their work; how much more easy must it not be supposed to be for the amateur with small experience to fall into errors of a like nature, and then to imagine that the fault lay with his plates?

It is not long ago that we were giving a little friendly help to an amateur who showed considerable aptitude in learning, but whom the fog demon had overtaken, as he said. His dark-room lantern we found to be not light-tight at the edges, and, at the same time, the one pane of glass was not sufficiently opaque to the more active rays. These faults were remedied with advantage to the negatives; but still there was fog. We gave him of our own plates, which we knew to be good; but, still fog. We carefully scrutinised his camera, but found no light hole, not even the most minute. A little surprised at our non-success, we took up the lens and at once saw where the trouble lay. At the back part of the mounting there was a flat band of polished metal—blackened it is true, but still possessing a polished surface, and capable of reflecting such an immense amount of light that it would have been a marvel if the plate had not been fogged. A piece of black velvet ribbon pasted over the reflecting rim entirely prevented any further trouble from this source.

We will conclude by pointing out a cause of fog which at times a large number of photographers have suffered from. We allude to the reflection, from the inner portion of the lens mount, of light received from the sky or clouds. If the camera be pointed at a view which embraces a considerable stretch of sky, it is absolutely necessary that the lens be screened with a shade of some kind. This need not be a permanent screen—a piece of cloth or velvet, a coat-sleeve, or, handiest of all, perhaps, a hat, will suffice; but it is imperative that the glare of the sky be not permitted to enter the lens. We

have seen such a very large number of negatives, otherwise most satisfactory, spoiled by this one cause only, that if our remarks but compel attention to be given to this subject alone they will have served a most excellent purpose.

PYROGALLIC ACID AND ITS PRESERVATION.

In former days when pyrogallie acid as a developing agent was almost invariably employed in a state of acidity, little or no trouble was experienced in its preservation, since, though the acid solution was known not to retain its developing energy for any lengthened period, it was an easy matter to make up a sufficient quantity to supply the day's requirements without incurring the trouble of repeated weighings of minute quantities for each plate developed. When, however, the alkaline method was introduced the circumstances were changed, and it became necessary to devise some means by which the pyro could be preserved in solution, or else to weigh out the quantity required for each operation, though the somewhat slipshod method crept into vogue of guessing at the quantity.

The earliest and at one time the almost universal plan adopted by dry-plate workers was to keep the pyro in concentrated alcoholic solution, the tendency to oxidation in that state being infinitely less than in aqueous solution. Accordingly a ninety-six grain solution in pure alcohol or rectified spirit became most commonly used, five minims representing one grain, though many preferred as more convenient a sixty grain solution, eight minims of which represented a grain, and so, greatly facilitated calculation in mixing the developer, since one minim to each drachm of developer formed a one-grain-to-the-ounce developer. Kept in this manner the solution retained its developing power for very long periods, and though it gradually darkened with time, the result appeared to be little detrimental to its subsequent action.

It is true there were periodical outcries against the employment of the discoloured solution, and sinister warnings of the dangers and uncertainties attending the practice, but we are not aware that they produced any great effect; however, to soothe the minds of those who disliked the change of colour, the method was published in a leading article in this JOURNAL some ten or twelve years ago of dissolving a minute quantity of citric acid in the alcohol, in order to still further arrest the oxidation and consequent discolouration of the pyro. The latter, though always prone to oxidation when in solution, especially in the presence of water, only exhibits a violent attraction for oxygen when it is rendered alkaline, in which condition it is one of the most powerful oxygen absorbents known. In rendering it very faintly acid its tendency to deterioration was thus arrested, and the publication referred to was, so far as we know, the first recognition of the use of acid for the special purpose.

With the advent of gelatine plates the necessity of preserving the pyro in solution was in more ways than one forced upon the notice of photographers. The large class of wet-plate workers who joined the ranks of gelatine had been accustomed to prepare their developer in quantity, and the practice of mixing it fresh for each plate not only proved irksome, but if the dry pyro had to be weighed out each time, was a practical impossibility in a busy establishment. The alcoholic solution, if it was ever tried by the ex-wet-plate workers, found little favour, as was only to be expected, for the quantity of alcohol thus introduced into the developer, small though it may be, causes it to flow on the gelatine surface in a "greasy" and semi-repellent manner, which they had been accustomed to accept

as a warning that the bath was out of order and required boiling to free it from excess of ether and alcohol.

The first step towards a preserved pyro solution for gelatine plates was made, we believe, in 1879 by a Mr. Barker, who published his formula in a letter in these columns; it consisted of the addition to the pyro solution of a minute quantity of nitric acid. This innovation at first gave rise to a considerable amount of comment amongst those who failed to see its object, though eventually it came to be recognised that though the acid was neutralised and rendered practically inert before the pyro was applied to the plate, still it had performed its function in preserving the pyrogallie solution in working order. Subsequently, Mr. A. Cowan published a formula in which citric acid played the part of preservative, and this, as well as the nitric acid method, are still adopted in many studios.

The next method was Mr. Herbert B. Berkeley's application of sulphite of sodium, and the commercial supply by the Platinotype Company of "sulpho-pyrogallol," or a solution of pyrogallol and sodium sulphite rendered acid. Some ten or eleven years ago, when experimenting with the late M. Sammann's "hydrosulphite developer," we noticed and commented upon the peculiar manner in which sodium sulphite, but more particularly the hydrosulphite, preserved the clearness of the pyro developer, even in its diluted state as used, the solution, after several hours' exposure to the atmosphere in a dish, acquiring only a clear pinkish-brown colouration, free from any of the muddiness so usual with ordinary alkaline pyro. But it was Mr. Berkeley who first called attention to the special value of sodium sulphite in connexion with gelatine plates; and though his recommendation escaped general notice for some little time, owing to the fact, no doubt, that the public failed to recognise its special usefulness, it is scarcely too much to say that at the present day nine out of ten photographers use sulphite.

Here it may be as well to point out where the difference arises between the use of acids and of sulphite of soda. As we have already mentioned, the acid is neutralised upon the addition of the alkali of the developer, and thenceforward becomes inert, or practically so, its only function, if any, being that of a restrainer. The acid, in fact, behaves purely and simply as a preservative of the stock solution of pyro, its functions in that direction ceasing directly the developer is mixed; consequently, however well the stock solution may keep, the mixed developer discolours as rapidly and as completely as if no acid had been employed. Hence, in a case of prolonged development, or, indeed, under any circumstances, the gelatine film becomes more or less stained by the formation within its pores of an insoluble deposit of oxidised pyro, which necessitates the subsequent application of an acid clearing solution to remove it, or at least to render it less obnoxious.

But with sulphite of soda the case is different; not only does it act as a perfect preservative of the pyro in stock solution, but after mixing with the alkali it still continues to exert its influence in counteracting the staining power of the developer. Though in the diluted state and in the presence of alkali it does not arrest the discolouration of the solution, it keeps the latter clear by preventing the formation of the insoluble deposit that in its absence is formed and constitutes the stain. Thus, except in the case of a very prolonged application, the film only requires a thorough washing to free it from any tendency to abnormal colouration instead of having to be treated with a special clearing solution.

Though, as has been said, the great majority of photographers now use sulphite, there are still those who decry its virtues and deny its efficacy or even attribute to it counter-valuing defects which they hold should forbid its use. Only a few weeks ago a statement was made at a provincial meeting to the effect that sulpho-pyrogallol is "uncertain." This we are prepared to contradict in the most unqualified manner provided the solution has been properly made at first. We are led to say this from the fact of having a few months ago used up a quantity of pyro solution preserved with sulphite of soda which had been made *upwards of five years*, yet which showed no loss of vigour nor any difference in behaviour from a solution newly made by the same formula. The colour had become rather dark, but that fault existed to a slight degree when it was freshly mixed, and the deepening of the tint was far less than would have been anticipated in the time mentioned, while the entire absence of any deposit or sediment argued well for the efficacy of the preservative.

A considerable amount of divergence of opinion is expressed as to whether the addition of sodium sulphite has any effect in retarding development. Much of this discrepancy arises, we are convinced, either from the employment of a bad sample of the sulphite or else from a defective method of employing it. Complaints are also heard of the discolouration of the solution even when fresh, but here again the fault lies with the operator rather than with the method. We have given a large amount of attention to the subject for many years past, and we are prepared to say that if the discolouration which is complained of is a great objection, a solution of pyro may be, if desired, kept for months, perhaps years, practically without the slightest discolouration or deterioration.

Nothing need be said regarding the use of bad sulphite, that is a fault for which there is now not the slightest excuse, as the proper article is readily obtained from any photographic chemist. But even in using the purest and best samples errors and discrepancies may arise. For instance, in the matter of colouration there is a right way as well as a wrong of mixing the solution. The so-called neutral samples are usually slightly alkaline, and directions have been over and over again given to neutralise the alkalinity *before* dissolving the pyro. If this be neglected, or even if it be done *after* dissolving the pyro, then it is not to be wondered at if some slight discolouration occur between the latter and the alkali, whereas, if directions were carefully followed, not the slightest discolouration in the sense of the term need take place. A pale, bright yellow tinge, such as many colourless salts take in solution, can scarcely be described as discolouration, which, as applied to pyro, is usually implied to mean a brown or black hue. If the solution be originally of the clear straw tint, it is not likely to further change.

With regard to the alleged slowing of development, it may chance that the charge is well founded, but not as against the sulphite itself. Thus, in his earlier instructions—and others have since followed him—Mr. Berkeley directed that the sulphite be neutralised with citric acid. Now, as we are all aware, the citrates are powerful retarders, so that we can readily imagine that sulphite of soda *plus* citrate of soda may retard the developer to an appreciable extent, when if some other acid—preferably sulphurous itself—had been used, no such effect would have occurred.

It is very easy to introduce complications and uncertainties into any process, but in this respect the method of mixing sulpho-pyrogallol appears to have been specially blessed, though

we think unnecessarily. But by attention to the principles upon which the "sulphite developer" is based, a perfectly reliable and unretarded preparation can undoubtedly be made.

THE Merchandise Marks Act is "An Act to consolidate and amend the law relating to Fraudulent Marks on Merchandise," to which the Royal assent has been given, has just been printed, and may now be obtained from the Queen's printers for twopence by any one who takes an interest in the matter, photographically or otherwise. The Act has been framed more especially with a view of checking a fraud upon certain British manufacturers, which for a long time has existed. It is the well-known custom of some foreign manufacturers to make up goods—textile fabrics in particular—in imitation of those made here, and sending them over to this country. Against this nothing can well be said. But they have also affixed to them the trade marks, and sometimes the actual names, of English makers for the purpose of enhancing their value, especially when the goods are for exportation. There is a special clause in the Act relating to watches, which may possibly apply to photographic lenses. It has of late years been very common for English watchmakers, or dealers, to purchase the movements abroad and to fit them into English-made cases, or in foreign ones bearing the English hall mark, and selling them as watches of English manufacture. When the new Act takes effect this practice will become illegal.

THE Act is very stringently worded, and the penalties under it are heavy. On summary conviction, for the first offence the fine is limited to twenty pounds, or in the case of imprisonment to a period of four months, and for the second offence the fine may be fifty pounds or the imprisonment six months. On conviction on an indictment the punishment may be both fine and imprisonment, the latter, in this case, being limited to two years. In cases of conviction the fraudulent goods become forfeited to the Crown.

ON the whole there is very little in the Act which is likely to affect photographers or photographic dealers. One of the clauses which is perhaps the most important to them is Clause 16, which reads as follows:—

"Whereas it is expedient to make further provision for prohibiting the importation of goods which, if sold, would be liable to forfeiture under this Act; be it therefore enacted as follows: (1). All such goods, and also all goods of foreign manufacture bearing any name or trade mark being, or purporting to be, the name or trade mark of any manufacturer, dealer, or trader in the United Kingdom, unless such name or trade mark is accompanied by a definite indication of the country in which the goods were made or produced, are hereby prohibited to be imported into the United Kingdom, and, subject to the provisions of this section, shall be included among goods prohibited to be imported as if they were specified in Section 42 of the Customs Consolidation Act of 1876."

From this we presume the Customs authorities will prohibit the importation of foreign lenses when they bear the names of English dealers, unless they also have on them the name of the country in which they are made. This, however, we imagine, will make but little difference, as most purchasers of lenses bearing dealers' names only know quite well that they are mostly made on the Continent, and that the dealer has merely selected them, and that he is responsible for their quality. An intimation on the mount that the lens was made abroad will not detract from its utility.

A CONSIDERABLE quantity of material used by photographers is imported into this country and sold by many dealers as being of English manufacture, at an enhanced price over what it would make if it were sold as of foreign make. Amongst such things may be enumerated albumenised paper, pyrogallol acid, and hyposulphite of soda. Under the new Act this procedure will be rendered illegal.

EVIDENTLY some photographers do not look upon faded photographs as being at all against their reputation. Some time ago we saw, on the barrow of a street hawker, a large number of very much faded portraits of celebrities, and bearing the name of a well-known London

house. These the man was offering for sale at a penny and twopence each. One might have surmised that it would have paid the photographer better, for the credit of the firm, to have destroyed these pictures rather than sold them for the trifling sum which they could possibly have obtained for them of the itinerant vendor. Such, however, does not appear to have been the case in this instance.

It is curious to note to what extent the demand photography has created for certain commodities has had in materially influencing their price as well as their quality. Opal glass is a notable example. Only a few years back this could scarcely be considered as an article of commerce, indeed the pot metal variety—for which at that time there was little or no use—could only be obtained from one or perhaps two sources, and then only at prices which were almost prohibitive. Now, however, the demand for it is so great and competition so keen, that its present price is little more than as many pence per square foot as it formerly was shillings. At the same time that the price has been so much reduced, its quality has been considerably improved. Opal glass is now used for many purposes other than photography. Pyrogallie acid is another instance. At the time that photography created a demand for this article it was little more than a chemical curiosity, and its price was enormous. At the present time a pound of "pyro" can be had for less than once had to be paid for half an ounce, and of far better quality. The uses of pyrogallie acid is not now confined entirely to protography.

MORE brilliant negatives might often be obtained if operators paid greater attention to the condition of the interior of their cameras—studio cameras, which are in constant use, in particular. By frequent dusting the black coating gets rubbed off, or the wood to some extent becomes polished. Consequently the light from the lens, which falls on the sides of the camera, instead of being absorbed is reflected and diffused, and much of it reaches the plate. Although, of course, this diffused light is exceedingly feeble, it is yet often sufficient, with a very sensitive plate, to have a marked effect on the brilliancy of the negative. If all studio cameras were lined with black velvet, instead of being, as they frequently are, imperfectly blacked, or partially polished, on the inside, it would tend towards a great improvement in the quality of the negatives. We would here bespeak special attention to our leading article on *Non-Chemical Fog* as bearing on this subject.

A VISIT TO THE ORDNANCE SURVEY OFFICE, SOUTHAMPTON.*

THE negative being finished, the next operation is that of obtaining from it an image in fatty ink, and afterwards transferring that to a zinc plate for printing from in a lithographic press. We shall now follow these operations through. Paper, of the bank post type, is coated with a solution of gelatine and bichromate of potash, and dried, of course, in the dark. The paper is then exposed behind the negative in an ordinary printing frame, until a distinct image is apparent. The exposure is made out of doors, preferably to sunlight, but diffused light is frequently employed. In winter, or when the light is very bad, the exposure is made to the electric light. The operators do not examine the prints, as experience has taught them to judge, from the appearance of the exposed edges of the paper, when they are sufficiently printed. In bright sunshine the exposure required is very brief, indeed then the operators usually wait beside the frame till the print is done. The paper being printed, the next operation is to coat it evenly with a fatty ink. This is done in the following manner:—

A zinc plate, or a lithographic stone—the former is used here—is evenly inked up with transfer ink thinned with turpentine, a leather roller being used for the purpose. The exposed paper is now laid face downwards on the inked surface, and the whole passed through a lithographic press several times, care being taken that the pressure is evenly distributed. By this means a more uniform coating of ink is secured than could be obtained by any other method. The image now requires developing. For this purpose it is taken back to the room where the paper was originally prepared, and floated face upwards

on water at a temperature of about 90° Fahr. After a time the unacted upon gelatine becomes softened and swells up; the print is then removed and laid face upward on a metal plate. Then the inked surface is carefully sponged over with a soft sponge, under a stream of tolerably warm water. This treatment removes the ink and the gelatine from all those portions which have not been acted upon by light, leaving the lines sharp and clear on a white or faint yellow ground. After the print has been fully developed it is well washed in cold water to remove all remaining traces of the unaltered bichromate, and then dried. It is now ready for transferring to the zinc plate, or to a lithographic stone, for the operation would be the same in either case.

At Southampton, however, stone is not used, the maps all being printed from zinc. The advantage of zinc over stone is very great, as all the plates are preserved—and they must number many thousands—it will be seen that, if stone were used, the immense amount of space it would occupy, to say nothing of its enormous weight. A large zinc plate weighs something like half a hundredweight, but a stone, the same size, would weigh three or four hundredweight. The stone would also cost six or eight times the price of the zinc.

The plates used are the eighth of an inch, or a little more, in thickness, and are all prepared on the premises. The zinc is of the Veille Montagne brand, which is found to be the best for the purpose. The plates are first of all well scraped with a tool made from a razor blade to take off the scale and any deep oxidation. They are then scrubbed down with pumice-stone and water, and afterwards smoothed with snake-stone; they are then ready for either polishing or graining. For general purposes grained plates are used. The grained surface is produced by grinding it with fine sand and a zinc muller.

The image in the fatty ink is transferred to the zinc in the following manner. The plate is placed on the bed of a lithographic press, and the transfer put between sheets of clean damp paper. While the transfer is moistening—for it must be borne in mind that while it is dry it is somewhat smaller than the finished map is to be—it is carefully gauged from time to time, and as soon as the expansion of the paper has reached the proper dimensions of the map it is at once laid, face downward, on the zinc, two or three sheets of paper are placed over it, and the whole is then passed several times through the press to "set off" the ink. Next the back of the transfer is sponged over with water, when, after soaking for a short time, the paper can be stripped off, leaving the ink upon the plate. It is now washed with water to remove any adherent fibres of paper, and dried. Next it is treated with a mixture of gum water, decoction of nut galls, and phosphoric acid, applied with a broad camel-hair brush. After resting for a few seconds, this is washed off. Now the surface is treated with turpentine to remove the transfer ink, and the plate is then ready for inking-up with ordinary ink and printing from by the usual method of zincographic printing. This, it is scarcely necessary to explain, is analogous to that of lithography—the zinc plate being merely a substitute for stone.

The printing, after the plates have been proved, is for the most part done in a gigantic litho machine by Furnivall—the largest size yet made. It runs at great speed, and prints two of the largest plates at a time. It is, as a matter of course, driven by a powerful steam engine. In the zincographic department, where this machine is, there is an immense rolling press for surfacing and glazing the paper; the rollers are nearly four feet long, and about eighteen or twenty inches in diameter. Also, there is a guillotine cutting machine, on a similar scale, for cutting the paper to the different sizes. This machine, as well as the rolling press, is, of course, worked by steam power. The plates, after they have been printed from, are stored away in racks formed of two grooved shelves, and enclosed with doors as a further protection. In front of the bottom shelf is fitted an iron anti-friction roller, which takes the weight of the plate while it is being placed in or is removed from the rack.

It was mentioned at the commencement of this article that all the different scales upon which the maps are issued are produced from one original drawing. Now a little consideration will show that if, say, the ten-foot scale were reduced to one inch, the roads, paths, and the more minute of the details—the names, &c., would be too small to be clearly distinguishable. Therefore it is necessary that they should be somewhat exaggerated in the smaller scales. The plan by

* Concluded from page 548.

which this is accomplished is most ingenious. It is known as the "blue process." A print on the larger scale is taken from the zinc plate in a very faint blue ink. Then the lines are traced much bolder in a strong black ink, and the roads and paths made broader. This is done by drawing them in with a ruling-pen, keeping some little distance outside the lines of the original. The artists who do this work are furnished with coloured plans to indicate the class of roads they have to deal with: thus, one colour represents a high road, another a by-lane, a third a footpath, and so on. The names are also put in on a larger scale; in fact, the map is entirely reproduced with the finer details on a holder scale generally, the blue print serving as a guide to accuracy. Much of this work is little more than mechanical, and requires comparatively but a small amount of skill to carry it out. For example, the names are printed in from type fixed in small holders, and houses and trees are put in by similar means. To explain all the ingenious contrivances and dodges resorted to in this department would take far more space than can be afforded. When the map is finished it is copied in the camera to the scale required, and as the light blue ink has about the same relative photographic value as the paper itself, this impression does not show in the finished negative.

Many of the maps are produced from engraved copperplates; indeed, the copperplate department is one of the most important in the establishment. Here some of the work is executed by etching, and some with the graver, but by whichever plan it is done it is a tedious and slow operation. Some of the larger plates, with the hills shaded, which are very full of detail, take as much as a couple of years, or more, to complete. In the hill-shaded maps the hills are first drawn in by artists on prints from the ordinary outline plate. In this work air brushes are now extensively employed, and very skilful the artists have become with them. Air brushes are also used for working direct on the copperplate as well as on the negative at times. At Southampton this useful apparatus is highly spoken of as a time saver. Although many of the maps are engraved, they are actually printed from zinc—the copperplates being used only to produce prints, which are afterwards transferred to zinc, from which the impressions issued are obtained.

The electrotyping department is an extensive one, and is most complete in every way. Here the copperplates are reproduced and other electrotyping work executed. The source of electricity is a Crompton dynamo machine, which is driven direct by a Williams's quick-speed engine. The dynamo has been specially constructed so that it can be used either for depositing or for lighting. When used for the former purpose it is run at a speed of about four hundred and thirty revolutions per minute. At this speed it will yield a current with the necessary electro motive force for the purpose required. From the room in which the engine and dynamo are situated we enter the depositing room. Here are about thirty troughs, each capable of taking the largest size plates, which measure thirty-eight inches by twenty-four. They are strongly made wooden vessels; some are lined with different waterproof cements, and some with lead. Several cements have been tried, but up to the present time lead has proved the most efficient for preventing leakage. The troughs are all mounted on pivots, and are kept continually rocking to and fro by a mechanical arrangement actuated by the same engine that drives the dynamo. The object of the rocking motion is to keep the solution slightly agitated and of uniform density, so as to ensure the deposited copper being of the same character throughout its thickness. The copper is deposited with the plates placed horizontally, the cathode, or reproduced plate, being uppermost, and the anode being below. By this means a more uniform deposition is obtained than when the plates are arranged vertically. So evenly, indeed, is the copper deposited here that many of the plates may be printed from direct without requiring the backs to be filed up to make them smooth. I saw several plates separated from the matrix and they were all of them most perfect both as regards uniformity and excellence of metal. The Waterhouse process is also in use here. In the depositing room is a milling machine of the latest type for rapidly trimming up the edges of the plates, so as to avoid the laborious method by filing. In a separate apartment are very complete appliances for testing the force and quantity of the electric current and for regulating them according to the work in hand, also for testing the quality of the deposited copper.

The electric light is in use at the Survey Office, the arc light being employed for printing the transfers from the negatives in dull weather and the incandescent light for illuminating some of the workrooms where daylight fails, the current for the latter being taken from a series of secondary batteries charged by a dynamo.

To give anything like a full description of the operations carried out at the Southampton establishment—or even to briefly allude to all their ramifications—would occupy far more space than is at my disposal. However, I have endeavoured to give some general idea of those most interesting to the photographic reader.

In concluding this notice I must express my appreciation of the extreme courtesy I met with from all associated with the establishment, and thank those gentlemen for the great pains and trouble they took to explain all connected with their different departments.

STEREOSCOPIC PHOTOGRAPHY AND ITS REVIVAL.

THERE has been latterly an apparent tendency in many quarters to return to the practice of stereoscopic work, which twenty years ago formed so prominent a branch of the amateur photographer's pastime; and I cannot help thinking this is as it should be, for a more charming class of picture than the stereoscopic, when properly executed, it is difficult to conceive. Small single pictures have their advantages, inasmuch as their production entails comparatively little labour, but their mean dimensions render them of little value when finished, for they are too small to frame and scarcely worth the trouble of mounting in a scrap-book. On the other hand, large pictures entail heavy and costly apparatus, to say nothing of the labour or cost of its transport, while there is a limit always to one's available wall-space, and pictures buried in portfolios cease to present much interest after one or two inspections.

But a well-executed stereoscopic slide is an entirely different thing; it necessitates no heavy nor expensive apparatus, while it may be made a "thing of beauty" and "a joy," if not "for ever," "for nearly ever," to parody Gilbert. The pleasure derivable in fact from the stereoscope extends far beyond the mere pictorial interest of the scenes depicted; they will bear examination and re-examination, new forms and combinations coming into relief constantly that pass unnoticed in the flat single picture. I am the possessor of a bundle of stereoscopic views, the production of myself and friends a quarter of a century ago, and though they have little that is attractive in their general appearance, being worn and shabby, and many of them having passed into the "sere and yellow," I can periodically derive an amount of real pleasure from going through those dilapidated old slides that all the exhibitions of the highest class of modern work would fail even to suggest. There may be some sentiment in the matter but it is not all so; the thoughts may fly back to friends who are gone, or to scenes that may never be re-enacted, but still the pictures themselves, as pictures, claim an amount of attention that has often set me promising that "next season I will go into stereo work again." Next season, alas! never comes; it is next *and* next, and I well remember that my last and really most practical attempt to revive the old love resulted in *four* stereoscopic pictures out of a season's work.

It is the custom to speak and write of the decadence of the stereoscope and of stereoscopic photography being due to the defective instruments and trashy and ill-executed pictures with which the market was at one time flooded. This has never appeared to me a reasonable explanation of the almost total neglect which has fallen upon "stereoscopy," for there were good and well-constructed instruments as there were choice subjects and properly mounted slides; the disease could certainly not spread by infection or contagion from the worthless ones. I can readily understand the lay public growing disgusted with the horrible productions of so-called art that used to be considered good enough to go with the stereoscope—inane and impossible groupings of frowsy French and German women, got up to represent glimpses of a home-life that the artist was an utter stranger to, or ridiculous attempts at comic scenes frequently conceived in the worst of taste. Then to find that after spending a quarter of an hour in looking into the stereoscope you contracted a violent headache and what promised to be a permanent squint, was not calculated to put anybody violently in love with an instrument which, however beauti-

ful it might be in theory, was certainly not conveniently or comfortably practical.

So far as the mere decline of the stereoscope in popular favour is concerned, I am ready to agree that it may have arisen from the causes stated; but as regards stereoscopic photography, I set the change down entirely to mere caprice, fashion, change of ideas—call it what you will. Those who formerly practised stereoscopic work got tired of it, went in for larger plates, or gave up photography altogether. Example is a great thing, and as one after another of the old practitioners dropped it, still others followed suit, and the newcomers had none to lead them into paths stereoscopic. In like manner I am firmly of opinion that it only requires somebody to make really and practically a fresh start in that direction, to let his stereo-camera be seen at some of the outdoor meetings, and his results at the indoor gatherings. I say it only wants the proper start to bring our old friend into greater favour than ever. What the practice of stereoscopic photography might become to-day as compared with twenty years ago can scarcely be realised in a moment, but at any rate the existing conditions are altogether favourable to its revival.

In the event of such revival we shall have practically the resuscitation of a lapsed industry, that of the manufacture of stereoscopes. Let us hope it will be conducted on more scientific lines than formerly, and let us further hope that during the years it has lain dormant the majority of the "old stock" may have disappeared both from "private life" and from the shelves of the dealers. This, I am afraid, is too much to be hoped, for we are nearly certain to find that, like Van Winkle-like, the manufacturers will wake up, if not with the identical old stock, at least with the same old patterns. If one of our leading societies would appoint a committee to report on the subject a type of instrument might easily be settled upon to form a standard, so to say, to which all respectable opticians would be glad to work; but so long as the matter is left in the hands of the "shopkeepers" there is little hope of improvement. I should imagine that in London, at any rate, if not in most of our large cities, there might be found a sufficient number of photographic amateurs interested in the stereoscope to undertake its revival by the formation of a club or society specially devoted to the production of stereoscopic work and to the improvement of the means and appliances thereto.

With regard to the stereoscope itself it is by no means a necessary condition to the production of a satisfactory instrument that it be an expensive one. One of the most convenient, and certainly the most comfortable of instruments I ever employed was one of the cheap folding description that cost me I think about half-a-crown. This I invariably used when mounting my slides, and for comfort, definition, and good stereoscopic effect it compared very favourably with a more pretentious instrument kept for "show" purposes, and still in existence, and which cost more pounds than the other did shillings. This, moreover, in spite of the fact that the lenses were simple double convex crown, while those of its aristocratic rival were duly achromatised. The latter instrument is not one that I should describe as a downright bad one, but it possesses certain defects, in common with most of even the best, that might easily be avoided.

It is of the usual conical-bodied box form, with silvered glass lifting reflector, and with screw arrangement for focussing. I have nothing whatever to say against the form of instrument, which, if properly constructed, may be without fault; but they very seldom are so constructed. In the one in question, for instance, as in almost every one of the class I ever met with, the reflector is ridiculously inadequate to the task of lighting the whole of the slide—I am speaking now, of course, of paper prints. Even when used directly and squarely opposite a window and close to it, in its best position, the reflector casts a curtain of shadow down either side of the picture, though the centre is well lit; but if, as very often happens, the side of the stereoscope is partially or wholly towards the light it is scarcely possible to see the picture, certainly with comfort.

This is an easily remediable defect, and one which I class amongst those of carelessness and ignorance on the part of the maker rather than as one of form. For instance, the body of the instrument I speak of is seven inches wide at its broadest part, i.e., where the slide is inserted, but the hinged wooden lid carrying the reflector leaves a margin of three-quarters of an inch at each side, or is an inch and a half shorter. The silvered glass reflector, however, is shorter still,

measuring at its widest part (for it, too, is shaped like the body of the instrument) four and a half inches, and at its narrowest three and three-quarters. Now, as the combined width of the two halves of a stereoscopic picture may be taken as six inches, it is difficult to see how a plane reflector of less than four inches can satisfactorily illuminate it. It is true that the left-hand side of one half and the right-hand side of the other are shaded, while the opposite sides are lighted, and that so the whole of the combined picture is more or less illuminated; but the difference between the centre and the edges is so great as to be positively disagreeable.

Now, if instead of so curtailing the size of the hinged flap—which, by the way, adds nothing to the neatness or ornamentation of the instrument—it had been carried to the extreme width of the framework, nothing more would have been needed, and my just cause of complaint would not have been written down. The instrument then would have been perfect, so far as lighting is concerned, for either paper or glass slides. In connexion with this question of lighting I may mention that a friend of mine some years ago had his stereoscope altered by cutting away the posterior part of the sides of the framework between the hinge of the reflector and the ground-glass back, leaving that portion of the instrument entirely open. This was a great assistance in lighting a paper slide, especially when sitting sideways to the light, but it almost ruined the instrument for transparencies, in order to satisfactorily view which it was necessary to cover the side openings with the hands.

Going from the body of the instrument to the lenses, these are, as I have said, achromatic, carefully matched and properly mounted, being provided with screw arrangement for focussing. This, I consider, quite sufficient, though some stereoscopes have an adjustment for altering the distance of the lenses apart. Considering that we have to deal with lenses of an inch and a quarter, or an inch and a half in diameter, this seems to me entirely superfluous, for if the lenses are set at a medium distance, say three inches between centre and centre, quite sufficient margin is allowed to suit eyes set at widely varying distances, as it is not absolutely requisite that the centre of the lens should be used. Three inches is a proper distance, as it places the lenses about opposite the centres of the two pictures; if that position be departed from to any great extent, one or other extremity of the picture gets beyond the range of comfortable vision.

So far for the principles of construction, and now for the defects of carelessness. The lenses are an inch and a quarter in diameter, and are mounted in tubes of an inch and a half diameter which slide in a pair of collars for focussing purposes. This necessitates a considerable length of tube, in this instance an inch and a half of clear slide, or a total length from the ornamental exterior eye-pieces of two inches and three-eighths, the lenses being fixed about midway. Now it results from this great length of tube that a large portion of the margin of each picture is cut off; this causes an uncomfortable and hazy idea that there is something floating in mid-air between the eye and the picture, and further if the attention be given to any objects at the edge of the picture they are indistinctly defined and devoid of stereoscopic relief. If one eye be closed it will be found that the circular tube cuts off the whole of the margin of each picture, but not symmetrically, that is to say, the same amount of subject is not shut off from each half; consequently in the combined picture a great portion of it is seen only by one eye, the centre being stereoscopic, but perhaps the greater portion being flat, indistinct, and in semi-darkness.

If the focussing adjustment is to be dependent upon sliding tubes, then those tubes should be of sufficient width in proportion to their length to prevent any portion of either image being cut off from the eye. But I greatly prefer a sliding or movable body for focussing; this may be as I have seen it, either a sliding wooden body, or what is neater as well as ornamental, extending bellows as in a camera. This does away with the necessity for any tube projecting behind the lens, and the consequent cutting off the corners of the picture, and it also enables an adjustable inner screen to be used for the purpose of shutting off the view of the sides and central partition of the instrument, which interfere greatly with the comfort of vision.

These are defects which will be found in very many stereoscopes of otherwise good construction. I have intentionally ignored the faults of really bad workmanship, because those, as a rule, may be

relied upon as being absent from the work of respectable firms. But the errors of carelessness, thoughtlessness, and ignorance, are in their way of just as much significance to the employer of the instrument, and these are the ones to which the least attention is likely to be given.

From the manufacture of the stereoscope to the production of the slides is but a short stride, and I shall next endeavour to show where the photographer may to some extent improve his ways.

C. BECKETT LLOYD.

(To be continued.)

WRITING AND DRAWING ON GLASS.

II.

Fine-ground glass is nearly as easy to work upon with pen and pencil as note paper. Such glass as is used for the focussing screens of cameras is suitable for this purpose; the roughness of the surface prevents to some extent the spreading of the ink, and by the latter being absorbed, as it were, into the minute depressions, we obtain blacker lines than we should get on smooth glass. Water-colours can be easily applied with a brush; it is best to mix them with a weak solution of sugar or gum, and to prepare the glass for the colours by a preliminary rub with a cloth made damp with the same fluid. After the writing is completed the appearance of plain, unground glass may be produced by varnishing it. Negative varnish, containing shellac, will do very well, or Canada balsam, thinned with benzole, may be used. The latter will take some hours to dry, during which it should be carefully protected from dust.

Matt varnish may be used to impart an artificial grained surface to smooth glass; it is easily made by dissolving ninety grains of gum sandarac and twenty grains of gum mastic in two ounces of ether, to which is added benzole, the amount of which may vary from half an ounce to one and a half ounces, according to the fineness of the matt required. This fluid is applied by pouring it on the cold plate; as soon as the varnish has set, the glass may be heated to ensure a firm and even grain. Upon this surface writing with a pen or pencil can be easily executed when dry; a syrup or gum arabic solution may be applied with a brush to restore the appearance of unground glass. As sandarac, the chief constituent of matt varnish, is soluble in methylated spirits, we cannot use collodion or shellac varnish to impart transparency, so we are obliged to adopt a water solution, such as syrup, as a protection for lead-pencil work, while in the case of ink Canada balsam may be used.

Resin is one of the substances that enable us to work with a plumbago point upon a smooth surface. A thin film of the gum is easily produced from a solution of it in turpentine or benzole, in the same way as gum dammar is used, and resin being of a brittle nature a little caoutchouc added to this solution will be an improvement. Resin is remarkable in its way, for it dissolves in methylated spirits as well as in turpentine. The former solvent (or spirits of wine) is the best for our purpose, as it contains no grease, and as Canada balsam, thinned with benzole, is also mixable with spirits of wine, a very small quantity of it may be added to the resin solution, to impart the requisite toughness and adhering power. A plain glass coated with this medium can be worked upon with pen and pencil, but it is not equal to gum dammar as a help to retouching, as the resin, though it is brittle when cold, is apt to become tacky when heated, which might occur in printing off a negative in the sun; another fault is that the resin film dissolves when the negative varnish is applied, so that work done by the lead pencil is exceedingly apt to become displaced. The only chance of a disturbance not taking place is when the resin film is very thin, and the pencil point is hard and sharp, so that the impression is driven into the gelatine basis.

Sugar, although not generally known as a medium for writing on glass, is perhaps the very best. I have used it for some months, and prefer it to any other substance, gum dammar included. It is suitable both for the lead pencil and for the pen. If a sketch in lead pencil upon clear glass is wanted as a lantern slide I would use a film of sugar, as I could produce thereon lines almost opaque in their blackness, and shading of any depth, combined with a singular freedom from grit. With a gum dammar film the lead is apt to break off in tiny pieces, and a shade, or half tone, cannot be easily produced free from black specks. If an ink sketch or writing is required, with

lines clear and distinct, then I would again use a sugar film, as I could produce thereon with ease the finest lines that a pen could trace. The ink, prepared itself with sugar, takes perfectly to the sugar surface, and shows no tendency to spread over the glass. There is no trouble in getting the ink to flow from the pen; sugar in solution is very tenacious of its continuity, and does not easily divide into drops, which cause blots in writing. Syrup has the same characteristics as thin treacle—we cannot divide treacle into small drops; if we pour it slowly from a bottle we obtain an attenuated thread of the substance. So syrup in a pen forms a narrow thread at the nib point, and being previously darkened with lampblack or other pigment, enables the finest black lines to be produced if required.

Saccharine matter exists in various well-known forms—there are white, brown, lump, crystallised, and moist sugars, and there is treacle. Treacle is a very good thing no doubt, but it is useless for our purpose, as it resembles calcium chloride in its power of absorbing moisture; it can be hardened by heat, but if exposed to the atmosphere it soon regains its pristine softness. Brown or moist sugar partakes of the nature of treacle to some extent; it can be dried by heat, but it absorbs a little moisture afterwards. White sugar, on the contrary, has little tendency to become softened by damp, and for an ink sketch on glass, a syrup made by dissolving white sugar in cold water is the best medium. Such a film, when perfectly dry, presents too hard and polished a surface for the lead pencil; by breathing on it the sugar becomes softer, and it then takes the lead perfectly. There is, however, some danger of overdoing the softening process, the result of which is that the lead point sinks into the film and causes a furrow instead of a clear line on the surface. So for the lead pencil I prefer to use white and brown sugar in equal parts, dissolved in cold water. This syrup may be spread on the glass either by pouring or with a brush, and the film may be quickly dried by heating the glass plate. But there is a better way of applying an even film of sugar to glass. Thin syrup has the curious property of being mixable with methylated spirits without causing the precipitation that occurs when gelatine or gum arabic is so treated. Thus we can add syrup to alcohol and coat a hot glass plate exactly as if we were using negative varnish. The film will be dry in a minute or so, and if the glass is perfectly clean the sugar will be equal in thickness throughout. It is best to mix the thin syrup with alcohol in equal proportions and to use it at once; if left at rest for some days a portion of the sugar is deposited in crystals on the sides of the containing bottle and the mixture does not then produce so even a film as at first. The glass should be made quite hot before pouring on the fluid, to secure the best result.

Sugar dissolved in water does not act exactly as a salt would do. The latter usually dissolves to a certain extent in cold water, and to a greater extent in boiling water. When the water cools a portion of the salt is precipitated. White sugar, so far, does the same. If a solution of salt in cold water is allowed to evaporate slowly the salt is gradually thrown down in crystals, but sugar so treated does not crystallise, it becomes of a thick pasty consistence and dries eventually as transparent as glass and with the same polished surface. So we can use syrup as a varnish, but salt we cannot.

A great advantage of the syrup foundation in writing on glass is that a shellac or mastic varnish can be applied as a protection against damp without the slightest fear of disturbing the design. We have seen that a resin film dissolves if varnished; a gum dammar film resists a spirit varnish better, but a pen-and-ink sketch thereon becomes woefully faint and attenuated. I presume that the sugary ink becomes softened under the hot varnish and shrinks up, so that the lines become finer. A similar sketch on a sugar basis is unaffected during the varnishing process.

ALBERT WM. SCOTT.

COLOURING AS APPLIED TO PHOTOGRAPHY.*

In the last issue of the JOURNAL we left off our list of colours at Prussian blue. We next come to—

Burnt Sienna.—Which may be described as an orange of a very rich and transparent brown hue. It is a most useful colour, and

* Continued from page 552.

besides being invaluable for many combinations with other colours is also very effective in painting warm complexions.

Mars Orange.—This is also a very clear and beautiful orange, partaking of the character of the burnt sienna, but free from the tendency to brownishness, which is a strong feature of the latter colour. It will therefore be found very valuable for bright sunny tints when applied in pale washes, and will be found unsurpassed for clearness of tone in its use for flesh painting.

Burnt Umber.—This colour will be found very useful for painting hair, also for draperies, &c.

Sepia.—Is a very valuable cool brown pigment. Its pale washes are extremely clear and transparent. It lends itself favourably to mixing with other colours, and by this means a great variety of valuable tints may be obtained.

Madder Brown.—This is a most beautiful colour, and as useful as it is beautiful. It may be described as a rich, *lakey*, russet brown. By its use the richest descriptions of shadows may be obtained when used in a fair degree of strength, while its paler tints exhibit extreme delicacy. Combined with cobalt it makes a delicate grey for the flesh, or soft tint for the shadows on the face, &c. It will be found also very effective for many of the darkest touches in the flesh. When the draperies are red it may be used in the dark shadows to lower the general tone, &c.

Neutral Tint.—A very useful grey, and especially adapted for combination with many other compound tints. In working up *monochromes* it will form a suitable tint when combined with carmine, or burnt carmine and sepia, or even black. Of course this must very naturally be greatly influenced by the colour of the photograph to be worked up. It is a matter of no small importance that in this regard the tints used should be in strict harmony with the photograph, otherwise a most unpleasant result will be the issue of all our labours.

Purple Madder.—A deep and warm purple of the greatest richness and intensity. By its use may be secured the greatest depth of shadow, free from all coldness of tone. It is a colour that works well, and is extremely useful for deep warm shadows and draperies generally.

Constant White.—This colour has not much body, and may be said to work indifferently, if not absolutely badly. It is only intended for the highest lights where white must be used, as for example the light on the tip of the nose, the light of the eye, &c. There is a *flake white* which is the principal white in oil painting, but I could never make my mind up to use it in water colour.

Chinese White.—This is a most valuable material. It works well in water, has a good body, and is reliable as to permanency. There is no other white which has up to now been used as a water colour which can approach it for these properties. It is needless to say that without these qualities it would be absolutely useless. It should, however, be used in moderation (as a water colour), and preference always given to transparent and pure colours. Of course there are times when a combination with white is not only advantageous but absolutely necessary, but when not so I recommend working without it. Messrs. Winsor & Newton's Permanent Chinese White I have always found most satisfactory and safe in every respect, while others which I have on occasion used (having no option at the time) I have not found to answer my purpose so well.

Lampblack.—A powerful opaque black, mixes exceedingly well with Chinese white as a body colour; it forms a splendid, indeed, I may say, the best ground for a black coat. There is no underlay of colour that it will not cover in this combination, so strong is it as a body colour.

Ivory Black.—This is the most transparent and richest black we have; in its paler washes it will be observed to possess a slight tendency to brown, but used to its full strength it is intense.

Now, these, I think, may be said to be the leading colours used in miniature painting, and by their aid there is no possible flesh, &c., which cannot be faithfully reproduced upon the ivory or Bristol board as the case may be. However, while we are on the selection of the colours, we may as well continue with such as will enable a student to paint any subject that may offer, be it portraiture or landscape, &c.

Naples Yellow.—A colour much used in flesh painting, but I do not recommend it. As I said before, I prefer using as much as possible the more transparent colours. I have seen some very pretty results

where this colour has been employed, but they will not last. There are two shades of this colour, light and deep.

Aureolin.—A rich, sunny yellow, very useful in many ways, and is transparent. It is a powerful yellow, and like all such should be used with care. Can be used for flesh, &c.

Lemon Yellow.—This is a light yellow, with fair amount of body. May be used for high lights in draperies.

Brown Pink.—A yellowish brown, rich and transparent. Can be used with advantage for glazing. I have found it last very well, but it is generally accepted as fugitive.

Cadmium.—There are three degrees of this colour. No. 1 is lightest; No. 2, useful, but still rather light; No. 3 is a deep, rich, and useful colour both in itself and in its combinations with other colours.

Cadmium Orange is a very rich colour, full of light and power.

Yellow Ochre.—This is a useful colour for producing atmospheric effects, as it seems to possess certain qualities of light which render it most effective for skies, &c. It is used in flesh, but, as I said before, I prefer Roman ochre.

Raw Sienna.—A very beautiful colour, a wash here and there in foliage giving great variety and relief. It will also combine with pink madder to make a very delicate flesh, and is generally a good and safe yellow to work into the face, that is on such portions of it where yellow seems to assert itself.

Vandyke Brown.—I do not think this colour wants a description, every one knows it.

Burnt Carmine.—A very deep crimson, useful in making tints for working in monochrome.

Emerald Green.—This colour is well known. It can be made great use of when judiciously treated. When artistically placed it can be of invaluable help to the flesh, and may sometimes be used as a kind of grey on the flesh itself. Many artists get considerable effect with it.

There are few, if any, effects that cannot be depicted with the assistance of the colours just enumerated. Of course there are many other pigments made which are useful and worth having, but they are not *necessary*. As I said, there are few tints that cannot be produced by combinations of the foregoing colours.

It is needless to say that there are essential differences between the art of miniature painting and that of colouring photographs, still, there are many important points in which they are very similar. Both the manipulation and management of the colours will be found to have a very close resemblance in both cases. It is necessary, therefore, that any one intending to direct their attention to the artistic colouring of photographs should at the outset know *something*, if not *everything*, regarding the principles upon which paintings in water colours are based.

There are many beginners who think that there is nothing to do but buy a box of colours, brushes, &c., and set to work and produce good results. Of course they are very soon undeceived. You may think this is not so, but I can vouch for the fact of a gentleman, now one of our leading photographers, who thought *oil painting* an easy matter. He had no very strong reason for holding this belief but the fact of seeing a certain very clever artist daily at his work. He concluded that what the artist could do so easily could not be difficult to him.

So thoroughly did this feeling take possession of him that, on the quiet, he bought himself a set of brushes and colours, &c., had a transparency made from a negative of one of his own children, and determined to make a picture. By the aid of the transparency and a sciopicon he made a fairly satisfactory sketch, and already ideas of the Academy floated across his mind. He took his sketch home and started to work. He was absolutely astounded to find he could not get along, or even get the colours on. He came up and saw the artist at his work, everything seemed easy, he determined to make one more try, but of course it terminated in absolute failure. This may appear romancing somewhat, but I can vouch for the accuracy of it.

No doubt the first thing that showed this gentleman the error of his ways is what would strike all beginners, their utter inability to get anything like a satisfactory result. A beginner who absolutely knows nothing of the principles of water-colouring, is often fairly amazed to find that, after mixing his colours to the desired tint, and

then washing them on to the photograph with the greatest care, he has not succeeded in gaining even a presentable result. On the contrary, the result is enough to make him foreswear ever wetting a brush again.

The fact is there is no part of the human face so flat in itself that it can be to any truthful extent represented by a simple *flat* wash, no matter how successfully passed over the photograph. It is necessary to have regard to the modelling, and all those gradations of light and shade caused by the natural undulations. The various gradations between the highest lights and the deepest shadows must be all considered and receive their proper treatment before any degree of satisfaction can possibly result. These various intermediate gradations are known as "demi-tints," "pearly tints," or greys. Now all these various gradations and intermediate greys, &c., cannot possibly be obtained by a first wash. No; this transparency and depth are only to be obtained by calling in the aid of "*hatching*," or "*stippling*," in order to place these necessary greys and "pearly tints" upon the local flesh tint which the *first wash* has already imparted to the photograph.

Without these greys there will be no roundness in the picture; everything will look flat and unnatural. It may be just as well to consider a little what is meant by the terms "*washing*," "*stippling*" and "*hatching*." Washing is using the colour in a liquid state and passing it *evenly* over the surface with broad strokes of the brush, and getting it as *evenly tinted* as possible. It is always best to mix this first tint as near to the desired strength as possible. A very good plan to enable you to judge the strength of the tint is to try it first on an old photograph. I suggest an old photograph because it has an advantage over a sheet of plain paper, inasmuch as it will enable you to better form an opinion as to the depth necessary to produce the desired effect over the *tone* of the photograph you are about to colour.

It must ever be borne in mind that these first washes must be pure and brilliant to a degree. It is an easy matter to lower the tone afterwards to almost any degree, but if once these primary tints are made dull and heavy there is no possible means of restoring their purity. If there be only a few spots here and there they can be taken away with the point of the brush or scraped away, the former for preference. High lights can be secured in the same manner before the *hatching* or *stippling* is proceeded with. REDMOND BARRETT.

PHOTOGRAPHY AND PHOTOGRAPHERS.

It is generally assumed that a photographer is one who practises photography, and to practise photography is to produce photographs (I can fancy the reader thinking every fool knows that). Still, in spite of the self-evident proposition, scores of persons calling themselves photographers do not produce photographs so understood of the people. They stop a short half-way, contented with the mere production of a negative, with or without assistance. This negative *may* produce a print fit to be looked at or it may not; there is a good deal of chance about it in many cases. The prints made by a great percentage of those who use the camera are very often short of perfection; this may be the result of improper printing *per se*, or it may be because the negative is utterly unfit for the purpose.

I believe it is infinitely more difficult to produce a perfect print than a perfect negative, chemically speaking. Given a negative of indifferent or thoroughly bad quality, no skill will be able to make a thoroughly good print from it, although, with a great deal of trouble, time, and patience, passable results may be obtained. In the first place, it is not very easy to decide off hand, even by those accustomed to it, what sort of prints a negative will give; very different looking negatives will produce equally good prints, and very passable looking negatives often very bad ones; it is not until a proof has been taken that a decided judgment can be made. To print well, all negatives must possess a good gradation of tone; this is imperative, and the tone must range from complete opacity to clear glass. The more perfect this gradation the better the negative.

With gelatine films there is one very disturbing influence, and that is variety of colour, more or less non-actinic, *colour very often taking the place of density*. The formation of a correct estimate of the printing value from the colour of the negative is most difficult, and few will venture, as I have just remarked, on a decided opinion without first seeing a rough proof. This colour influence was almost entirely absent with wet collodion negatives; at any rate, the puzzling variety that now obtains with gelatine was unknown, and the consequence

was a negative could be at once assigned to its proper class, and its printing capacity pretty accurately estimated before any proof was taken from it. We, however, now have to do with gelatine films almost entirely, and sometimes judging by the wet collodion standard, negatives that appear almost everything they should *not* be with, with a little dodging, give surprisingly good results.

The public estimate a photograph *only in the form of a print*, the negative, to them at least, is thought no more of than the type of the printer as they read the resulting letterpress. This being the case, it seems marvellous that any one can treat printing as a matter of quite secondary importance, looking upon it as a mere drudgery, and simple as turning a grindstone, which I need scarcely say is about as wide of the mark as it very well can be. A negative of *some sort or other* can be taken by anybody who likes to try, and no experience is required, but the difficulty of making a good print is undoubtedly much greater. The importance of a thorough knowledge of printing is consequently vastly augmented by the unequal printing value of the negatives. Instead of being a commonplace, everyday occupation for boys and girls, as many wish it was, it taxes the experience of the most capable workers to the utmost to make those rich and delicate pictures that have caused photography to become so popular.

At *no time* has first-class printing been an easy matter, and now the great variation in quality of gelatine plates, as I have just remarked, enhances the difficulties tenfold. If I might venture an opinion I should say there are no trade printers that have not found out this to their annoyance and disgust, that is, if they take any pride in turning out good work. The quantities of impracticable rubbish called negatives from which prints are required must be enormous. Fortunately for the printers, those who take them are not very exacting, and prints far below the ordinary standard of excellence are considered good enough. Taking the negative is but a beginning, and if all those who take up photography would set themselves to do something more than this elementary work, by making their own prints, they would *soon find out how good or how bad their negatives were*, and the careful performance of this most essential part of the process would act as a check and indication of what to do and avoid in making the negatives. When a man can succeed in regularly producing thoroughly good prints, and *only then*, should he depute the task of printing to others. All doctoring or improvement of the negative ought to be the work of the taker of the negative, it being part and parcel of the same.

In printing, certain conditions have to be observed and conformed to in order to produce anything like a satisfactory result. It will be seen by the following notes that silver printing exacts care and skill of no mean order to produce first-class results. The paper is the first consideration, and much depends on this being of good quality and free from defects. If it is prepared at home, it is sensitised by floating a definite time on a solution of silver nitrate of a suitable strength for the paper used, deficiency in this respect leads to a variety of troubles. Excessive strength, on the contrary, leads to few, or rather to one, that of bronzing in the shadows. The strong bath facilitates the subsequent operation of toning and improves the quality of the print in the end. The paper is now dried and cut up into suitable sizes, laid on the negatives and exposed to the light. Here comes in judgment. A too long-continued action of the light will make heavy, unsatisfactory pictures, and too short, flat, washed-out looking things. Each negative must be printed to suit *itself* and the *subject*—light, delicate impressions will be best in some cases, and strong, bright ones in another. Very much of the beauty of result depends on this part of the printing, and during which any dodging that may be required has to be resorted to, such as shading part of the negative where it prints too dark for the rest of the subject, or printing some parts more than others for effect, tinting down such portions that print too light and are out of harmony with the rest, in fact using the light as a pencil to make up for deficiencies in the original negative, or to subdue something that would otherwise injure the effect of the finished work. It will be seen there is plenty of scope for the exercise of skill and artistic ability, in fact quite as much, if not more, but in another form, than that required for taking the negative.

After this comes the toning, a shoal on which many get stranded, depending as it does on the previous processes of sensitising and washing. Too little printing gives poor, flat results; a foggy, thin negative does the same in an exaggerated degree; every different quality of negative makes a different coloured print. Then, again, the prints will bleach more at one time than another; this is partly depending on the light in which the prints were made, and partly on the condition of the toning bath. This leads to irregularity of colour, although the apparent depth of the printing is the same in all instances.

Again, there is the fading that sometimes takes place in the fixing bath, when apparently things have been all right up to that time. After fixing, there is only one trouble to be guarded against, and that is blisters, to which some paper is particularly liable—a good wash finishes the process, so far as actually making the prints, which, when dried and trimmed, are ready for the mounting. Finally, the prints must be carefully looked over, and any objectionable light spot touched out with colour approximating to that of the print, containing sufficient gum to give an equal amount of glaze with the rest of the albumen surface, then, and only then, can the photograph be considered completed.

I hope to have shown by this slight sketch of the process of printing that it is well worth the attention of any who use the camera, and that to really be a photographer the ability to print *must* equal that of taking the negative. EDWARD DUNMORE.

GELATINO-BROMIDE PAPER AS A BASIS FOR FINISHED WORK.

[American Convention.]

AFTER some introductory remarks, the author proceeded as follows:—

CRAYON FINISHING.

As crayon is the most popular material, I will commence with that. The materials wanted are Conte crayon saucé No. 1 and 3, Conte crayon ordinary, and No. 0 and 1 superfine in wood, three or four leather stumps of various sizes, one dozen paper stippling stumps, a stick of ordinary office ink-eraser, and two rubber stumps, soft and medium, some pumice-stone very finely powdered, and a quantity of carded cotton.

The print to be worked should be printed fully out, that is, it should have every gradation from high light to deepest shadow, and should look a little darker than wanted for a plain print. It should be mounted upon a muslin-covered stretcher, as the best effects cannot be obtained if the print is mounted upon cardboard. Great care should be taken that no starch gets upon the face of the print during mounting.

Material for Stumping.—Take one stick of the Conte crayon saucé and crush it finely; two sticks of No. 1 Conte crayon must be finely powdered by rubbing them upon glass or sand paper No. 1, and be intimately mixed with the Conte saucé.

Place the print flat upon the table. Have a piece of cardboard by the side of the print. Take a tuft of cotton and dip it into the mixture, and rub it upon the cardboard to spread and equalise it; then transfer it to the background of the print, rubbing gently with a circular movement right up and over the edges of both face and figure. Do not be afraid of spoiling your print, as it is easily taken off with the rubber. In putting in your background, see that the darkest part is kept low just over the shoulders, and bring the shaded side of the background up to the lighted side of the face, which should contrast with the shaded side of the face and figure, while a bold shadow should be put in just over the shoulder to balance and represent the cast shadow. When you have got in your background roughly, put aside your cotton and straighten out the three longest fingers on the right hand and rub lightly all over. This is the most important part of the background. The fingers must feel the crayon roll evenly under them, and if they do not, but catch the paper instead, there is not enough No. 1 Conte in the mixture, and more must be added till a gritty feeling is obtained; then go ahead, rubbing all over the background with a circular movement, taking no trouble to keep off the face or any other part of the picture. If you wish to darken any part, rub the tips of the fingers with the same mixture, and transfer the crayon taken up on to the part of the print which needs it, and rub it in. An even tint can be rubbed all over a black coat or other dark drapery in this manner, shadows deepened, and the hair strengthened. In fact, all that is usually done by the chamois skin upon solar prints can be done with the fingers upon the bromide paper. Now take a large piece of clean cotton, and after knocking the superfluous crayon off the picture, rub evenly all over. This will considerably lighten all the crayon; but if not light enough, or there are any inequalities in the background, dust a little pumice powder evenly all over, and go over it all again with the finger, using more pumice powder whenever you wish to lighten, but being careful not to use too much, as an excessive use of pumice powder will rub down and flatten the grain of the paper. If these directions have been carefully followed, the background will show a beautiful grain or stipple, so like a hand stipple that it has puzzled experts to detect the means adopted for producing it. This grain can be varied by the method of handling. With a light rub a large open grain can be obtained, and the heavier the rubbing the smaller the grain will be. Now rub again with clean cotton, and place the picture upon an easel. With an ink-eraser clean the edges of the background and blend with the cotton. At this stage any amount of artistic effect can be put in and taken out of the background. The stump can be used to hatch in broad effects, and the ink-eraser to take out lights, &c. This part of the work it is impossible to describe. Individual taste and experience are the only guides, and the beginner had better not attempt too much in that line till experience has given him confidence.

Having thus far gotten your background in order, we will proceed with the figure. Begin to clean up the face with the rubber stump, taking out the high lights upon forehead, cheek-bones, and chin, and blend with a small tuft of cotton. In some cases this handy little tool may be made more effective by dipping it just before use into the powdered pumice; thus, by the use of the rubber stump and cotton blender the modelling of the face can be worked out, and the beginner will now be surprised to find how much lighter the face appears; in fact, it lacks decision, which we will now proceed to put in. Take one of the stippling stumps, and, rubbing it in the saucé before described, mark in the pupils of the eyes, the lines of the eyelash, the shadows under the eyebrows, the brows themselves, the nostrils, and the shadows under the chin, blending all with cotton. Next deepen the shadows of hair and drapery with one of the leather stumps, blending also with cotton or the fingers, now on the deepest shadows of the drapery and everywhere where decisive touches are wanted. Mark in strongly with Conte No. 3 crayon and blend with the fingers. Do not touch these shadows with the cotton or you will destroy their firmness. When you have got thus far you will be surprised what an effect you have obtained with little labour, and now any amount of finish can be obtained by working with the point of crayons No. 1 and 0. The filling in of the face is best accomplished with No. 0, and should be done in the same manner as retouching a negative, filling in and softening breaks or inequalities in the gradations. The No. 1 is useful in rounding and marking the eyes, eyebrows, hair, &c. White drapery should never be touched with white crayon. Any amount of light can be taken out by the hardest rubber, and dark shadows can be lightened with it. Great effect can be obtained by first covering the white drapery with a light tint of crayon saucé rubbed evenly all over with cotton, and the lights taken out with the soft rubber. Lace can be made out in this manner with great effect, and with far better harmony than can be obtained by the use of white chalk, which gives a metallic effect, and for that reason should only be used upon the high lights of jewellery, &c. But, as a rule, the less white chalk used the better.

RETOUCHING OR MENDING.

There is another method of finishing bromide prints which may prove acceptable to those photographers who do not want them finished in crayon, but yet want some kind of finishing or retouching to improve the plain prints, which can be done simply and cheaply by the usual help in the studio. The spotting or mending the white spots upon bromide prints can be done with India ink to which has been added just enough Payne's grey to neutralise the brownish tint of the ink. With this the pupils of the eyes, the line of the lash, the eyebrows, and, in fact, every shadow can be deepened, taking care not to lay the colour on too thick at first. It is better to get the effects by repeated washes than to get them at once, as you are likely to get harsh edges if the colour is laid on too deeply. Having in this way got in your strength, mend the face and fill in any breaks in the gradations with a Faber retouching pencil. If the picture is a vignette, and the blending should be uneven or too abrupt, you can correct that by rubbing upon the parts to be blended pure graphite or plumbago in this manner. You can buy the graphite or plumbago (it is known by both names) at any artists' material store. It is sold in bars or short sticks, something like Indian ink; or, failing that, go into the kitchen and levy contribution upon your wife's stove polish. Take a tuft of cotton and rub upon the bar or cake of graphite till it is well covered and shiny, then gently rub upon the part to be filled up. This matches both in surface and colour the bromide print. Shadows in white drapery can be deepened, and a tint put all over it so that high lights can be taken out with the rubber, just as I have before described in the crayon work.

Another dodge for improving the shadows of a bromide print is to rub over them a solution of wax in benzine, and polish with a brisk rub with Canton flannel. To be more definite, take one and a half ounces of bleached beeswax, cut it into small pieces, and put into a bottle with eight ounces of benzine. When the wax is dissolved, apply the mixture to the shadows with a piece of rag, and after the benzine has evaporated rub briskly over the part with Canton flannel till it shines. You will be astonished at the result. The buried details scarcely seen will show themselves clear and distinct, and the shadows will be deepened and made more transparent. This can also be applied all over the print, and gives a surface with a slight gloss, bringing out details and making the print fifty per cent. more brilliant, without the objectionable gloss which you see on a varnished print.

FINISHING IN WATER COLOUR.

Of course, in a paper like this I would not begin to give anything like an exhaustive set of directions for colour finishing, so these remarks must be directed to those who know something about finishing in colours upon other surfaces. You will notice that in the two first methods of finishing I say nothing about preparing the surface of the paper, simply because there is no preparation required. For water colours the surface must be prepared by hardening the gelatine surface with alum. Without this hardening the surface is too receptive, the colour being held when the brush just touches, and any attempt to blend or soften will result in pulling up the print from the surface of the paper; but after the application of the alum you can do anything with it. You can wash in or wash out, and even take out lights with water and rubbing with a cloth,

without raising the surface. The alum solution is one ounce powdered alum to twenty ounces of water. This is swabbed over the surface of the mounted print and left to dry, when it is ready for working upon.

Good effects upon vignetted prints can be obtained with very little expenditure of time by rubbing the background with coloured pastel, the half hard kind, to which has been added just enough powdered pumice-stone to make the mixture feel gritty. Proceed exactly as described for crayon. You can rub one colour over the other, and so get effects of combined tints which are very pleasing. I set my palette for flesh painting with pink madder, vermilion, yellow ochre, cobalt blue, and the various browns for hair, &c. I just put a flat wash all over the flesh of a tint made by combining the pink madder with yellow ochre in different quantities, according to the complexion—a dark complexion needing more yellow, and a fair one more of the pink. Having put in my flesh washes, I next proceed to wash over the shadows with light washes of vermilion to kill the black of the prints. Next put in the carnations on the cheeks and lips; after this the face must be finished by hatching and stippling—the edges of all shadows being stippled with grey composed of cobalt and yellow ochre, the blue predominating on the forehead and upper part of the face, and the yellow on the lower part. All the usual methods of working water colours upon drawing paper, or on any other photographic surface, can be used on bromide paper after it has been prepared with the alum solution.

PASTEL.

There is no preparation of the surface needed for pastel. It takes hold of the surface as well as any other paper, and can be worked by any of the usual methods. I like a good vigorous print with clean lights, and half tints and shadows not too black. I first lay in my dead colouring with soft French pastel, covering the photograph with the flesh tints as near as possible with the proper strengths, lightening up the shadows with vermilion and yellow, then hatching with half hard and finishing with hard Swiss crayons. An effect of great finish is obtained by this method.

OIL.

For painting in oil upon a paper print, a sizing must be used to prevent the oil in the colours getting into and staining the paper, which it will do in spite of the gelatine. The sizing solution is ten grains of gelatine to one ounce of water, brushed evenly over the print with a broad camel-hair brush. As with pastel, so with oil. I prefer a good, clear, strong print, and work somewhat in the same manner, viz., from the shadows to the lights, painting over the photographic shadow with warm transparent colours, and using opaque colours on lights, half lights, and reflexes, finishing with solid colour on the high lights, and cool greys on the edges of the shadows.

G. H. CROUGHTON.

ADVERTISING AND PRICES.

[American Convention.]

DOUBTLESS others will have many papers treating on the theory and practice of the various processes worked in the daily avocations of the photographer. In this case it will be well to let us consider for a few minutes a subject that is uppermost in the minds of many, even if we are unable to remedy the evils that photographers are suffering from. But I am convinced that many among you will go home disappointed if this subject is not broached. There are some who say it is absolutely useless to touch it; that it is treading on dangerous ground; that it is an evil that must work its own remedy; that every one has a right to carry on his business as he pleases; and that, notwithstanding anything that may be said here, no reform can be made practical that will be adopted that can benefit the craft. I wish to suggest that at least an effort can be made in this direction. No reforms have ever been accomplished without overcoming frequently insurmountable and formidable obstacles. Let us see if we cannot find a Gladstone and a Parnell to aid us; or, perhaps, in the minds of many, a severe coercion act would be more applicable in our case, as being more effective to aid us in voting out the pests that are a curse to our beautiful calling. There is no country in the world where competition is keener than among the photographers of the United States, nor is there a country on the face of the earth where the effects of cut-throat prices and cheap-Johnism have been more seriously felt by the members of the profession.

To many here this subject is of great import. From the advertisements of photographers inserted in the Chicago daily papers, the business of photographers for hundreds of miles around is affected and that most seriously. In no other country nor in any other city are to be read such disgraceful and unprofessional advertisements as are to be found most frequently in our leading newspapers, and especially on Sunday. It is a disgrace to our leading journals to allow their columns, for the sake of a few dollars, to be used to abuse members of a reputable profession, as is frequently done right in this city. You cannot find a member of any other profession but the photographic who delights in publicly degrading and insulting his competitors. Sometimes the attacks are of such a personal character that in many European and South American countries the proprietors of the newspaper, as well as the advertiser, would be held responsible and justly chastised or "called out" and made to account for his actions; but in this free and enlightened country the cowardly

and base advertiser who has a few dollars to throw away can at will hold up the followers of the same profession in which he makes a living to the ridicule of the public. If we want the public to respect our calling we must respect ourselves. Of late this mania for large and vulgar advertisements is spreading, and there is no knowing where and when it will end. The majority of our successful photographers advertise very little in the daily papers, and, if at all, generally a neat and respectful advertisement without any allusion to their competitors. Other professional men rarely make any reference to one another. It would not matter so much to the whole fraternity what an individual might occasionally say about another in the same business, but the dire effects of advertising cut-throat prices is felt throughout the neighbouring States that are adjacent to a city like Chicago, whose papers are sent out in thousands on the morning trains.

The disgustingly-illustrated advertisements of some photographers cannot help but attract the attention of the unthinking. The members of this Association might pass certain resolutions as to what they consider professional etiquette as regards advertising, but it is to be feared it would have no effect on the photographers who were endeavouring to drag into the mire the whole profession.

I consider this matter of advertising, and the serious question of prices, should be brought up for discussion at least. It would be well, on an occasion like this, to let the public know that photographs are being made by some at prices that lead only to ruin and degradation of the man who makes them, and that the man who respects himself sufficiently to obtain higher and remunerative prices is the artist who is looked up to and, in the long run, patronised by those who have been disgusted with the work done by the majority of those who give their professional services for little or nothing. The great difficulty in grappling with this question is that portraits made at low rates are much too good for the money, and we are reluctantly compelled to acknowledge that they satisfy a certain class of people who do not go into the artistic merits of a photograph. To them a print from any negative is a portrait. One remedy, as proposed by Mr. Scotford, could be made a success if the majority of the members of this Association would take hold of it, subscribe sufficient working capital, and provided practical business men were given the management of it. Perhaps it will be well to explain in as few words as possible that Mr. Scotford's idea was that a joint-stock company should be formed by photographers, they owning all stock. When any photographer in any town or city undertakes to make a cut, the company steps in and rents a gallery of a member and aids him to meet the cut, or they erect one themselves and run it until the man who started the cut gets sick of it and agrees to abide by an established rate. My object in bringing this subject before you is not to propose a remedy myself, but with the view that by calling your attention to it some among you might suggest a manner of alleviating the suffering of those who are unfortunate in having small galleries and unremunerative businesses, owing principally to the cut-throat propensities of a few who do not care what becomes of his neighbour.

It is well known that many will use the hackneyed phrase with regard to this price question, "What are you going to do about it?" My answer will be: "Let us tackle it and wrestle with it, for if it is left alone it will drag on for years." It would be well for the fraternity to do away with the pernicious system of giving chromos and life-size portraits with every dozen cabinets.

It does seem strange that there should be less unity among the photographic profession with regard to a scale of prices than in almost any other calling. The hod-carrier, carpenter, and even the bootblack do not cut prices like photographers. There should be more unity among those who work in photographic studios. If assistants were banded together they would get better wages and could better their condition. To avoid a waste of time in discussion on the subject of prices, it might be well to appoint a committee of three proprietors of galleries to make an investigation and report, if possible before the close of this Convention, on the price question.

C. GENTILE.

CONTINENTAL PHOTOGRAPHY.

[Translations and Abridgments.]

MISCELLANEOUS ITEMS.

AN exhibition is now open at Boulogne-sur-Mer, and a portion of its space is devoted to photography.

The name of the new photographic organization in Vienna is the *Club der Amateur Photographen*.

To accelerate the speed of gelatino-bromide plates, says the *Photographische Mittheilungen*, M. Himly puts them, before development, into a solution of one-three-hundredth of nitroprusside of sodium. The results are analogous to those given by thiosulphate of soda much diluted (one-five-thousandth), but with the great advantage that nitroprusside of sodium will work with the pyrogallol developer.

Dr. Eder states that gelatine plates, rendered sensitive to orange and red rays by a bath of cyanine, are less rapid than ordinary plates, or plates treated with erythrosine. They require four or five times as long an exposure. They will not keep well more than eight or fifteen

days; reduction begins at their edges, and gradually extends over the whole surface.—*Photographische Mittheilungen*.

M. Adolphe Martin has exhibited to the French Photographic Society three wide-angle lenses, the curves of which he stated to have been calculated with the greatest care, so that chromatic aberration was totally corrected, and the central and marginal rays brought to a focus at the same points. The lens of 15 cm. focal length sharply covered a plate 13×18 cm.; that of 19 cm. focal length, a plate of 18×24 cm.; and of 28.5 cm. a plate of 24×30 cm.—*Bulletin de la Société Française de Photographie*.

The London correspondent of *Le Moniteur de la Photographie* says that it was desired to ascertain if the same classes of clouds had the same general forms all the world over, which problem could be solved by photography only, and that the Hon. Ralph Abercrombie has presented to the Royal Society of London a series of photographs of clouds taken in different parts of the world, replying to the question at issue in the affirmative.

THE EFFECTS OF HEAT ON THE LATENT IMAGE.

Herr Gædicke has carried on a series of experiments which prove that an exposed gelatino-bromide plate may be submitted to a somewhat high temperature without destruction of the latent image; when, however, a temperature of from 85° C. to 90° C. is reached, an action takes place which results in fog in development. This fog is more or less intense. A temperature of 100° C. results in so much fog that the image is masked therewith.

If instead of experimenting with plates in a dry state the film is first expanded with water, the latent image will not disappear with heat until the gelatine begins to melt, and then it is only deformed by movements of the liquid. This takes place even when the plate is kept in a truly horizontal position.

An image can be formed upon a liquid film of gelatine emulsion upon a horizontal plate; it may be developed after the gelatine has set.—*Photographische Mittheilungen*.

EXPERIMENTS WITH PLATINUM PRINTS.

Herr E. Vogel says that to give a glossy surface to platinum prints they may merely be dipped in a weak solution of gelatine containing a little alcohol, after which the gelatine is hardened by a bath of chrome alum.

If a higher glaze be desired powdered shellac dissolved in a cold, concentrated solution of borax may be employed; it takes several days to dissolve. The print should be floated upon this bath, then suspended to dry.

If still more glaze be desired the proof may be soaked in a solution of gelatine, then squeegeed face downwards upon a sheet of glass coated with collodion of one per cent. When dry the print is stripped off the glass.—*Photographische Mittheilungen*.

FRENCH PRIZES FOR PHOTOGRAPHIC PRINTS.

The Committee of Administration of the Photographic Society of France has resolved that prints presented to the Society at its ten meetings between November, 1887, and August, 1888, will be taken into consideration in the following matter, if their producers make a demand to that effect. In the course of August, 1888, after the meeting in that month, the prints will be submitted to a jury of five members appointed at the general meeting. This jury will have at its disposal (1), a silver gilt medal, (2), two silver medals, and, (3), six bronze medals, to be awarded in recognition of the prints thought to be most remarkable. The medals will be distributed at the meeting in September, 1888. The Society reserves to itself the right of using the pictures for which medals have been granted in such publications as it thinks proper, and particularly for the illustration of its own journal.

PHOTOGRAPHY AT THE PARIS EXHIBITION.

In the general classification of the French Universal Exhibition of 1889, photography is included in Group II., "Education and Instruction—Materials and Processes of the Liberal Arts." Photography forms Class 12 of this group.

The Committee of Admission, which has already commenced its work, will meet on the first Thursday of each month in one of the salons of the buildings of the Administration, Avenue de Labourdonnais, Champ-de-Mars, Paris, to attend to communications received. Those who wish to exhibit should apply early. Forms of application for space may be obtained of the members of the Committee of Admission, also of the Minister of Commerce, 20, Rue de Varennes, Paris, and when filled up should be posted to the Director General of the Universal Exhibition of 1889, 20, Rue de Varennes, Paris.—*Bulletin de la Société Française de Photographie*.

INTERESTING OPTICAL APPARATUS DEVISED BY ANSCHÜTZ.

Herr Stolze, in relation to the instantaneous photographs by Ottomar Anschütz, as seen in the *phénakisticope*, says that he was deputed by

the Minister of Public Instruction of Prussia to assist in experiments made by Herr Anschütz to represent animals in motion by means of photography. Herr Anschütz placed around the circumference of a vertical disc of steel from fourteen to ninety-four photographs, ten centimetres square, printed as transparencies upon glass. Behind the most elevated part of the disc a plate of opal glass was fixed, behind which again was a Geisler's vacuum tube of spiral form, through which induction sparks were flashed at the rate of thirty a second. When the disc was made to turn with proper velocity a spark illuminated in succession each of the revolving transparencies, and the impressions thus produced upon the retina of the observer became combined in such a fashion as to convey the sensation of the movement of the animals pictured. In this way Anschütz illustrated the movements of the horse. The play of the muscles of the horse could be perfectly seen—the movements of the ears, mane, tail, and so on.—*Photographisches Wochenblatt*.

"SOLID BROMINE."

A correspondent of *Le Moniteur de la Photographie* speaks of a new preparation by Mr. A. Brand, which he calls "solid bromine." It is simply silica impregnated with a certain quantity of bromine. The silica of infusoria (*diesselguhr*) is taken, mixed with ten per cent. of chalk or soda, and charged with bromine; then little sticks of the mixture are made, seven millimetres in diameter, which contain about one gramme of bromine to each centimetre of length; larger sticks of fifteen millimetres' diameter contain three grammes of bromine per centimetre. By these means given quantities of bromine can be introduced into a solution, in which the silica sinks, and from which it can afterwards easily be separated. It is a means of enabling bromine to be used in the laboratory without risk to health from its vapour.

PHOTOGRAPHING FIREWORKS.

M. Barral, of the Faculty of Medicine at Lyons, has been experimenting on the photographing of fireworks, and taking note of the photogenic action of travelling flames of different colours. He had good opportunities of so doing, the principal fireworks of the 14th of July *fête* being let off within fifty metres of his house. He exposed his plates for fifteen seconds, in order to obtain, upon a black ground, a sufficient number of trails upon each. Henderson's 13×18 mm. plates were used, with a No. 3 Derogy lens, without a diaphragm. He obtained the best results when he used an iron developer.—*Revue Photographique*.

PREPARING PAINTINGS FOR COPYING.

Before photographing a painting, its peculiarities should be examined, especially in the matter whether it is or is not varnished; but in either case it will often be found that particular colours in it have a matt appearance, known as *embu*. These *embus* may be rendered harmless by passing over the painting a sponge or brush charged with the albumen of an egg which has been beaten into a froth, and then allowed to repose; two or three drops of ammonia should be added, to impart keeping qualities. With very old pictures the same result may be obtained by rubbing them lightly with a flannel upon which one drop of the finest salad oil has been allowed to fall; the opposite side of the piece of flannel to that on which the drop of oil falls is the side which should be applied to the painting.—*L'Amateur Photographe*.

EXHIBITION OF THE ROYAL CORNWALL POLYTECHNIC SOCIETY.

LIST OF AWARDS.

- 1st Silver Medal.—H. P. Robinson, W. J. Byrne, F. A. Green.
2nd Silver Medal.—B. Wyles, J. Lafayette, W. H. Hyslop.
1st Bronze Medal.—F. Whaley (special), Warwick Brookes, Morgan & Kidd, Dr. E. W. Alabone, W. J. A. Grant, Rev. H. B. Hare.
2nd Bronze Medal.—G. Dunson, F. B. Dagley.
Highly Commended.—J. M. Brown.

Our Editorial Table.

VARIOUS APPLIANCES FOR RETOUCHING NEGATIVES AND PRINTS.

By L. & C. HARDTMUTH, Vienna; and 2, Long-lane, Smithfield, London.

MESSRS. HARDTMUTH have been going in for the special requirements of photographers, and among other things they have prepared an exceedingly comprehensive set of pencils for retouchers. These are made of compressed lead—by what means compressed we do not stay to inquire. It is enough to say that between their six-II grade (which are as hard as can be) on the one extreme, and their six-B

grade on the other—this latter being softness and blackness itself—the one merging into the other through a graduated amount of twelve pencils, there is such a degree of diversity as to more than satisfy the most fastidious of retouchers. This series of *Graphite Comprimé* will form a useful addition to the appliances of the retoucher.

But this firm is not confining itself to retouching pencils, for it also sends us an assorted selection of hard chalks, which we find on trial to be exceedingly useful for touching-up prints produced on bromide paper or platinotypes.

A CONVENTION GROUP.

By WILLIAM CROOKE, Edinburgh.

WHEN the members of the Convention of the Photographers of the United Kingdom visited Edinburgh they were photographed in a group by Mr. W. Crooke, of that city, the location selected for that purpose being Craigmillar. Mr. Crooke has sent us a print in platinum from the large negative he obtained on that occasion. As a work of art it is admirable, while it is doubly valuable on account of the excellent likenesses of the visitors, added to whom are several leading members of the Edinburgh Society. Mr. Crooke informs us that he supplies these large prints (unmounted) at 10s. per copy.

“ 15 ...	London and Provincial	Mason's Hall, Basinghall-street.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

ON Thursday, September 1, at the adjourned special meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. J. Traill Taylor presided.

The new rules were passed, and the meeting, at a late hour, was made ordinary.

The CHAIRMAN said that Mr. Gray was present to give particulars about the lightning photograph questioned at the previous meeting.

Mr. W. E. DEBENHAM stated that remarkable scientific facts were accumulating in the photographic world; at another society a member ascribed a photographic effect to an increased rotation of the earth upon its axis, and at their own previous meeting it had been urged that a lightning flash could turn back upon itself in a loop.

Mr. J. GRAY exhibited the negative, and said that it was taken at Brixton at nine o'clock at night. The lens was uncapped for about two minutes; he rather thought that there were two flashes. The general direction was horizontal, so the discharge seemed to be from cloud to cloud.

Mr. W. H. HARRISON stated that a flash might have one general direction, yet from the effect of perspective seem to turn back upon itself in a loop. He illustrated this by means of a wire twisted into a rough somewhat spiral form, and said that in meteorological research it was evidently necessary that each flash should be photographed from different points of view.

Correspondence.

✉ Correspondents should never write on both sides of the paper.

THE NOMENCLATURE OF LENSES.

To the EDITORS.

GENTLEMEN,—Will you allow me to add a few remarks on the above subject and the discussion that arose from the protest of Messrs. Voigtländer & Son? I feel confident that every one who has fairly considered the question, will acknowledge that the spirit of the protest is just; and that the designation of particular manufactures should be respected as proprietary.

Messrs. Perken, Son, & Rayment are only one of many dealers and some (perhaps) manufacturers, who have of late systematically advertised lenses styled similarly to inventions to which particular names were given by the originator. I refer to the terms “Rapid Rectilinear” and

“Wide-Angle Rectilinear.” You, gentlemen, and many of your readers, are well aware of the fact that not long ago the above terms, as applied to photographic lenses, were often used *alone*, and were as distinctive of manufacture by Dallmeyer, as were the “Rapid Symmetrical” and “Portable Symmetrical” lenses of Ross, the “Aplanats” of Steinheil, and the “Euryscopes” of Voigtländer.

While fully appreciating the truth of the maxim of “imitation” in its relation to genuine and sincere flattery, I cannot but commiserate those whose vocabulary does not permit an independent selection of titles suited to their own articles.

I understand that Messrs. Marion & Co. have been engraving lenses “Rapid Rectilinear,” but it is due to them to say that they have discontinued doing so, acknowledging the title as proprietary.—I am, yours, &c.,
19, Bloomsbury-street, W.C. THOS. R. DALLMEYER.

FIFTY SITTINGS FOR A PORTRAIT.

To the EDITORS.

GENTLEMEN,—I would not trouble you with any further remarks upon this subject, but I feel assured the letter of your correspondent, John Patrick, should not be passed over in silence. He takes what seems a broad and fair view of the matter, and I feel sure would not be satisfied if his opinions did not receive recognition. There is much in his letter which is very true and with which I quite agree, but there are also parts which I cannot let pass without protest.

I must disagree with the opinion that, as it were, “honours are divided” in this matter between the gentleman who disputed my original assertion in the JOURNAL (page 406) and myself. If I am right he must be wrong, because he, “A Painter,” said I was. However, I think on all hands we can cry “Enough!” as regards this, for every correspondent acknowledges that photography *can* and *does* help the artists of to-day, more or less.

There is a suggestion, if I read aright, that certain artists could not be bound by the trammels of photography. Now I am of opinion that a first-rate artist can use photography as a help, and that such help will not in the least hamper his style and treatment of a picture. I cannot, for example, fancy that Sir F. Leighton, in the ease mentioned by your correspondent (Mr. H. S. Moberly), was in the least hampered when once he made a fair start upon his work. I would also feel inclined to wager that no ordinary spectator would notice anything in the finished picture which would lead him to suppose that Sir F. Leighton did not paint it under his usual conditions and free from the *help* or, as some people think, the *hampering influence* of photography.

In the fifth paragraph of your correspondent's letter he describes a certain class of artists who could not draw sufficiently true to nature “to make a striking likeness.” Don't you think in such a case these artists should not pose as *portrait* painters, but rather give their sole attention to colour and the production of “fancy heads,” &c., where *likeness* is not a consideration? But all this gets away from the original point at issue; viz., “*Can or can not photography be a help to the artist?*” It does not matter whether for drawing, expression, or saving of sittings, but simply, Can it be a *help* in any way? I said it *could*—nay, *was*. “A Painter” contradicted my assertion. I will leave it to your correspondent, John Patrick, to say if there be any difficulty as to *who* is right; but there can be only *one*.—I am, yours, &c.,

REDMOND BARRETT.

PAINTERS v. PHOTOGRAPHERS.

To the EDITORS.

GENTLEMEN,—In recent issues of the JOURNAL have appeared a correspondence wherein is renewed the ever-recurring warfare between artists and “photographers.” This time the subject of dispute is, whether photography is of service to artists, and it seems to me that the attitude assumed by the artists towards photography is very ungracious, whilst the photographers, in a spirit of exaggerated self-defence born of the unjust disdain they have been accustomed to receive at the hands of the more haughty professors of the palette, enter the contest in blind anger, and miss the point of their adversaries' contention.

That photography is of use to artists ought not to be denied, but those benefited by it should come forward and acknowledge the fact. The most signal instance of its usefulness is in the case of instantaneous photography, which has made such rapid strides of late, and I hope that by its aid we shall see produced many paintings representing scenes of lifelike activity, such as would have been almost impossible to artists who flourished before the advent of this most remarkable branch of photography. To depict life in motion has hitherto been a matter of such difficulty that only men of the highest talent could hope to surmount it. In reviewing a collection of modern paintings, who has not been struck by the prevalence of works whose subjects show a superabundance of repose? Over all there hangs a languid air of wearisome *inertia*. This is the result of the restricted conditions under which the artists have had to labour, the most imperative of them being that the drawing and painting be correct in all the details. Now to secure this they have been compelled to copy from living models, who did but simulate action; and there is an obvious distinction between the springiness and “go” of a figure that is actually moving, and the dummy-like rigidity of one that

is merely holding itself, or being propped up, in a position to imitate the movement which it is intended to delineate. It is in this direction that photography is now able to lend the most peculiar and invaluable assistance to the artist. Certainly, art has resources of her own, to display and heighten the effect of transient motion, but in the light afforded by recent example of instantaneous photography we find that even her happiest efforts are often far from being *en rapport* with nature.

Instantaneous photography, rightly employed by the painter, is able to release him from conventional bonds, and to enlarge very greatly his range of subjects, and such aid should be received by the artist with gratitude and praise. Photography is a valuable handmaid to the landscape artist, and furnishes him with memoranda of natural effects. These memoranda are easily produced, and with such swiftness can they record the appearance of fleeting cloud, glancing rays, waving foliage, rippling brook, and rolling sea-waves, that they possess a truthfulness, an unity, and a spontaneity, which cannot be equalled by the most facile sketcher.

That the mechanical artist, as, for instance, the engraver, is indebted to photography for much help, is so well known that we need not dwell on it here; suffice it to mention in passing, that all the visible universe contains may come to him in morsels from time to time, and for illustrations of many kinds photography does, in an inimitable manner, all that first part of his work which formerly he would have entrusted to a draughtsman.

We come now to a consideration of the case of a most interesting personage, the artist who is going to paint, let us say, a human head, in proper colours, as a portrait. Now, a little transparent colouring applied to a good photograph will often result in a very pleasing and natural picture at a small cost of time and labour, and may be far preferable to the ordinary work from nature of a mediocre artist; but, if we are to suppose that the very best result is sought for, regardless of expense, and that a really good artist can be employed, then we are prepared to admit that he may not find photography of much use to him, because if he is able to colour a photograph in a perfectly satisfactory manner, especially with anything approaching to opaque materials, it is very likely he will be competent to do equally good, or better work, from life, always supposing his choice be perfectly free, and that his model is able to sit still, which consideration excludes young children. No artist with a commission to paint a picture of one, or many, of these most charming, but mercurial, of nature's productions would, in his right senses, hesitate to avail himself in some measure of the assistance of photography.

Certainly, although a good model be procurable, some preliminary sittings may be avoided by beginning the painting from a photograph, and bringing it forward to a certain stage before requiring the attendance of the sitter; but then the saving of time and trouble effected will be rather for the benefit of the sitter than the artist, except in the case where the model has to be paid so much an hour, when a considerable sum of money might be saved to the artist.

Then there are cases common enough where the actual presence of the subject, whether by death or other cause, is presented, and perhaps some small photograph is the only clue which will help us to rescue from oblivion the memory of a departed form. In this noble and gratifying task the photographic enlarger and the portrait painter can work together, and as a result of their joint labours they may possibly produce an image which, glowing with the colours of life and by its natural dimensions and intelligent expression, may seem indeed a most perfect "counterfeit presentment" and "a pretty mocking of the life," helping to nourish "the sad remembrance fondly kept," forming the most cherished *souvenir*, to be placed foremost among the household gods, and to be preserved with veneration as a heirloom as long as canvas and paint will hold together.

Meanwhile, photography might be more frequently utilised, even in drawing the human figure, than it is now, were it not for certain objections, some of which I will proceed to enumerate. In the first place, we have, as a rule, the shadows on the flesh so much blacker or lower in tone than they appear in nature; but this defect will disappear in measure as we advance in the perfection and general adoption of orthochromatic photography.

Distortion of the contours, and gross exaggeration of the perspective, are grave faults and serious drawbacks, which might be greatly obviated; and if even they could not be eliminated might be at least reduced to a minimum, if photographers generally would be more awake to the enormity of the evil, and went in for securing good "drawing" even though it be at the expense of some other quality.

Lastly, we see the artist knocking his shins against a very hard stumbling-block that has only of late been placed in the way by some ill-advised persons, who seem to think a great deal of their clumsy article—in fact, as it was rather expensive they are inclined to consider it quite an ornament. I refer to the "*rétoche*," as this is now become usually excessive in quantity, and displays more or less ignorance of all that is "art." I cannot wonder if the educated artist has a great objection to it, and, where ideality and softness are required, would prefer to do them himself.

Having shown that photography is in many respects of great utility to artists, I will not stay now to speak of certain variations of the proposition which occur to me much further than to commend them to the attention of the reader; they are—the utility of artists to photography, and the utility of photography to art itself. I cannot, however, refrain

from suggesting that it is in close connexion with art that photography is destined to be of the highest usefulness to the world, not by rendering unnecessary the calling of the artist, but supplementing it and helping to distribute among the multitude that thirsts for beauty a plentiful supply of good and cheap art.

It being a fact, then, that the two sisters in art, photography and painting, have grown so useful and necessary to each other, let there be no discord between them, but rather may they continue in their career of mutual benefit, and for ever go, "like Juno's swans, coupled and inseparable."—I am, yours, &c.,

F. WILCOCKSON.

26, Charleston-road, Ranelagh, Dublin, August 31, 1887.

To the Editors.

GENTLEMEN,—There appeared in the JOURNAL from the pen of "Free Lance" some strong remarks relative to my assertion "that a portrait painter cannot receive any assistance by aid of photography," so I think myself entitled to beg of you to excuse a few more lines about the subject as reply.

That there are plenty of portraits worked up with the aid of photographs, alas! no one can deny, and I distinctly acknowledged this fact. But I said such work could only be accepted as an imitation without value relative to art. That this assertion is not so very audacious as it may possibly to some persons appear, I hope in the following quotations to show. It will not be disputed that by painting a portrait the use of one or more photographs can, at the best and uttermost, only help the painter by furnishing him with an accurate design in outlines and details, and by this enable him to finish a picture closely resembling the original, or, as the artist calls it, an *imitation*, respectively a *realistic work*. Now Mr. D. C. Thomson speaks about such paintings in an article headed *Realism in Painting*, published in the *Art Journal* of August, 1880, page 226, thus: "Again, the art of portraiture in painting may be realistic, as, for instance, such a likeness that when a dog comes into the room he would go up to the picture, taking it to be his master. This, to some people, is the highest art, and they speak of the painter as if he were a world's wonder. But such a picture is not, properly speaking, art—it is simply a process which any fairly gifted person may accomplish, and, in fact, it is almost mechanical." Further, he asserts: "But realism is very apt to descend into imitation, and imitation is the very lowest form of art."

In the same sense a famous French art critic, Mons. A. L'Hornier writes: "L'art n'est pas une étude de la réalité positive — c'est une recherche de la vérité idéale." To produce a work of art, the artist is bound to study nature in her eternal beauty; the holy spirit of the Creator, which prevails in all nature, must inspire his beginning and his end, and no mechanical process will help to catch the poetic sublimity of form and colour to procure a likeness of nature as art demands.

I agree with "Free Lance" that this subject presents another distinctly fraudulent aspect, but it seems to me very difficult to draw the line where the fraud begins. May I nevertheless say of the case related, where the faces of the pictures went afterwards all black, that the blackening of a picture is not a proof that it must be necessarily a photograph painted over with oil colours. There are different causes which produce such effects, and, as the artist of the portraits was one of repute, I would rather presume the blackening was of another origin than such an ignominious fraud, and could have been, perhaps, easily restored. With sincere thanks again for your indulgence—I am, yours, &c.,

A PAINTER.

Liverpool, September 5, 1887.

Exchange Column.

* * No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Will exchange an eight-air musical box for an 8½x6½ tourist camera.—Address, GEORGE C. RADFORD, The Studio, Mansfield.

Studio camera, lens, and stand, tripod, and mounts in various colours and sizes, offered for limelight apparatus.—Address, F. JACKSON, 16, St. Alban's-terrace, Sherwood-street, Nottingham.

Will exchange portable dark tent, stongly made, with all fittings, for hot roller burnisher, or half-plate tourist camera, or rapid rectilinear lens.—Address, J. T. M., 26, Mile-street, Barnley, Lancashire.

I will exchange a Grubb c2 portrait lens and a Grubb A* aplanatic for a lantern and slides or whole-plate portable set complete; also a whole-plate rapid rectilinear lens for studio accessories.—Address, W. T. WHEATER, Ford House, Villiers-road, Bristol.

Whole-plate and half-plate portrait lenses, stereoscopic camera, two 12x10 dipping baths, head and body rest, rolling press for cabinets, &c.; wanted, exchange in modern outdoor apparatus with lenses for whole-plates.—Address, C. MURRAY, 4, Mulgrave-road, Sutton, Surrey.

Will exchange an interior background in good condition for a seascape or interior ditto; also, wanted, a 7½x5 or half-plate portable camera by good maker, with three or more double backs, in exchange for 10x8 ditto with one single and one double back.—Address, WHITEHOUSE, Photographer, Dolgelly, North Wales.

Camera, 8x5, with three double and one single dark slides, stereoscopic division, extra front boards, waterproof case, nine-inch landscape lens, two pairs stereoscopic lenses, namely, landscape and rectilinear; also quarter-plate camera with eight double slides and one single ditto, four, five, seven, and nine-inch landscape lenses, fitting, and mounts, with shutter; two tripod stands. Any of the above in exchange for microscopes.—Address, W. I. CHADWICK, Brooklands, Manchester.

I will exchange Grubb whole-plate A lens and a burnisher, ten-and-a-half-inch roller, gas apparatus for heating tool, for Sciopticon with four double condensers.—Address, T. H. MACKENZIE, 8, Palermo-street, Springburn, Glasgow.

Answers to Correspondents.

NOTICE.—Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a NOM DE PLUME as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

PHOTOGRAPHS REGISTERED :—

G. Denny, 21, St. Sidwell-street, Exeter.—*Photograph of Exeter Theatre Royal.*

C. Watson, 4, Kirkgate, Ripon.—*Photograph of The Most Honourable the Marquis of Ripon.*

T. C. (Oldham).—It is very much a matter of taste. By both systems excellent results may be obtained when properly worked.

G. SMITH asks how to throw down the gold from old toning baths.—The gold may be precipitated simply by the addition to the bath of a solution of protosulphate of iron.

J. DUTTON.—Unless we knew how the negative was produced or what caused it to become weak and yellow it is impossible to suggest a remedy. Has it been intensified? if so, with what?

H. T. Y. asks if and where in England he can procure the *Bulletin Belge de la Photographie* and *Photographisches Archiv*.—Any of the foreign journals may be obtained through Messrs. Trübner & Co., Ludgate-hill.

A. D. R.—We know nothing more of the process than was communicated by our correspondent. If the bichloride of copper were applied before the platinum the image would be converted into chloride of silver.

ELECTRO.—1. The plan used at the Ordnance Survey Office is described on another page. That, perhaps, will answer your purpose.—2. Nothing but what is contained in works on etching and engraving, of which there are several.

L. F. C. asks: "When strengthening a gold toning bath, should thirty grains of acetate of soda be added each time to every grain of gold?"—It is not necessary to add acetate of soda each time an addition of gold is made. Some must, however, be added occasionally.

ENLARGEMENT.—Enlargements can be made equally good by gaslight as by daylight. It is only a question of duration of exposure. The condensers usually employed for concentrating the light on the stage of a theatre are not suitable for the production of photographic enlargements.

CHAS. STEPHENS.—Some portions, such as the wharf with the people on it, being sharp, and other portions, such as the steamer, being in duplicate, we infer that the steamer has moved during exposure. Examine the negative crucially and see if this be not the case. We refer to the steamboat at end of wharf.

J. PALFREY writes: "Will you be good enough to inform me what varnish or medium is used to tint albumen prints with transparent oils, or is it done with varnish colours ready prepared?"—If the print be sized with a weak solution of gelatine no other preparation is necessary. Ordinary oil colours can then be employed.

MR. W. A. WATTS desires us to correct an error which has crept into his abstract of the discussion at the last meeting of the Liverpool Amateur Photographic Association. He reported Mr. Sayce as saying that he had taken a week to develop a collodio-albumen plate, whereas he said he had seen a print from a plate which had taken a week to develop.

RETOUCHER.—Without making an analysis of the particular sample of paper we could not say. It is not made for photographic purposes, and probably the different batches may vary with regard to their applicability in photography. We have used some samples of it successfully, but have failed with others. You had better make a trial with what you have with different strengths of bath.

BATH says: "I have an old wet plate dipper bath enclosed in mahogany case which we have lately used as a fixing (hypo) bath, the glass of which has got slightly cracked, and of course the hypo solution keeps constantly wasting; can you inform us in your next issue what would be the best packing to use to stop the leakage?"—The best plan will be to fill the space between the glass vessel and the wooden case with melted paraffine; this will prevent leakage. There is no photographic difference; they are simply trade terms for lenses possessing similar properties.

NEUCHÂTEL.—1. Messrs. Trübner & Co., Ludgate-hill, will procure it for you.—2. Bronzing of the prints may be due to more than one cause. One reason is the silver bath being too strong for the sample of paper used. A weaker bath should be employed. Over density in the negative is also a cause of bronzing.—3. We are in no way responsible for the advertisements which appear in our columns. It is certainly a great hardship that you should lose your specimens, but we fear we cannot help you. Why not write to the police authorities of the district? they may possibly know the whereabouts of the owner of the studio.

GRIMSBY.—1. If the equivalent foci of the various lenses named, or of any other lens not named, be the same, then will the sizes of the images projected on the screen be similar.—2. The same in both cases.—3. When a lens is capable of introducing a very near object then does the importance given to such near object tend to dwarf the mountains and other objects at a distance; but in every case will lenses of the same focus delineate the objects on the same scale of magnitude, although some will include a greater amount of subject than others, and, in the case of foreground, thus by contrast diminish the distance. Thanks for enclosure, which was put to the use intended and left no residues.

LOLO says: "I shall be glad to know of a reliable toning bath. I make mine in the following way:—Acetate of soda, sixty grains; water, sixteen ounces; gold, two drachms; and I am not successful. I keep it three days before using, but something goes wrong with it. I wish to obtain a purple hue. My gold solution is carefully kept from the light."—If our correspondent is really using two drachms of chloride of gold to sixty grains of acetate of soda the failure is easily accounted for. We presume, however, that two drachms of a solution containing one grain to the drachm has been employed. If this is the case the proportions are right. Perhaps the negatives are not of the right character to yield purple tones or the paper may be at fault.

A. S. writes: "How can I stain ordinary window glass a deep non-actinic red?"—2. Some time ago you told me to use liver of sulphur to throw down silver in hypo; I did as recommended. I find the water still black, although clear, and a sediment in the bottom of the tub. I suppose the sediment to be the silver thrown down; but is it necessary to get the water white to get all the silver out? Although black, it has been beautifully clear for weeks."—In reply: 1. Coat the glass with varnish or collodion in which aurine or, preferably, chrysoidine has been dissolved.—2. If a further addition of liver of sulphur does not produce turbidity the whole of the silver has been precipitated. The sediment at the bottom of the cask is sulphide of silver.

A. A. C. asks: "How many grains of gold (actual gold) are there in a fifteen-grain tube of the chloride? I have been making some of the latter according to Mr. Forrest's instructions in this year's BRITISH JOURNAL PHOTOGRAPHIC ALMANAC. He there states that a half sovereign will make one hundred and twenty grains of chloride; now, as the half sovereign weighs about sixty to sixty-one grains, this makes the reaction at variance with the atomic weights of gold and chlorine. Sixty grains of gold should, theoretically, make about ninety to ninety-two grains of the chloride. Then, again, in many fifteen-grain tubes of gold there is a printed label to the effect that the contents are guaranteed to contain seven grains of pure gold; surely they should contain ten grains of that substance. Again, if a half sovereign only really makes ninety grains it is cheaper to buy AuCl_3 ready made, whereas Mr. Forrest shows a saving of forty per cent. by making it at home."—In reply: It is impossible to say how many grains of gold there are in a commercial fifteen-grain tube of chloride of gold. If it be guaranteed to contain seven grains, of course it should contain that quantity. A half sovereign weighs about sixty-one grains, but it must be borne in mind that only fifty-six of this is really gold, the remainder being alloy; hence a half sovereign will yield eighty-six grains of pure chloride, the intrinsic value of which is ten shillings. However, chemically pure chloride of gold is not an article of commerce, it always contains free acid and water. If it be a double salt, say of soda or potassium and gold, then the other constituent must be estimated for. On page 805 of our volume for last year our correspondent will find an article on the subject.

REGATTA puts the following questions: "1. When paper negatives are oiled the oil spoils the resulting picture. Is there any skin or transparent film which might be placed between the sensitised paper and negative? if so, where can it be obtained, and at what price?—2. Is the process of dry plate making one which requires great skill? Must the room in which the glass is coated with the emulsion be absolutely free from all actinic light? I mean more so than an ordinary dark room. Is it cheaper in the end for an amateur to make or buy dry plates of a large size?—3. Large dry plates are sold at very high rates; are the paper negatives of recent invention sold at the same rate or cheaper than glass plates?—4. It sometimes happens when enlarging that the heat from the lantern is so excessive as to cause the film of the negative to crack or blister; how can this be avoided?—5. How should the lenses in an ordinary combination portrait tube be arranged for, in other words, what is the order in which the lenses are placed?—Reply: 1. A thin film of gelatine may be interposed; this will probably avert the evil. Thin sheets of gelatine may be obtained from most fancy box makers.—2. The light in the room must be perfectly non-actinic. Some little skill and judgment is required in making dry plates. With regard to the cost, this will of course depend upon the value our correspondent sets upon his time. Unless he uses a large number of plates he will find it far cheaper to purchase them than set up the appliances for making them.—3. Paper is the less costly.—4. A glass tank containing a solution of alum interposed will stop off a large amount of the heat.—5. The portrait combination should be used without alteration, but arranged so that the back lens is next the negative to be enlarged.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting, September 14, 1887, will be on *Simple Cameras*. Saturday outing at Rickmansworth. Train, Moorgate-street at ten minutes past two o'clock.

A CORRESPONDENT sends us the following:—"Necessity is the mother of invention. A photographer in the north of London, suffering a drought of feeble trade and superfluity in family, while possessing but a little faded memorial card to his best and only lens, still persists in placarding his studio with an announcement, 'Children taken instantaneously.' This 'specialty,' and all other work, is made by a portrait combination consisting of a small lens from a cheap telescope mounted in a battered condensed milk tin tied to the camera by string, the whole covered from the gaze of the curious by a brownie black shawl. A fact. Ye lovers of expensive lenses, please note!"

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1428. VOL. XXXIV.—SEPTEMBER 16, 1887.

AN UNSUSPECTED CAUSE OF FADING.

DURING the past year several examples of fading in silver prints, somewhat extraordinary in character, have been brought under our notice. We may, in commencing, explain that we have used the term extraordinary because, at first sight, and with the data supplied, it was difficult to account for such rapid fading as that in question. But when, however, the facts were inquired into, there was really no mystery in the matter, and a little consideration would have shown, to any one conversant with the subject, that what occurred was precisely what might have been anticipated—indeed, it could not well have been otherwise.

The particular phase of fading now in view is that where prints which have been mounted show spots in a few weeks afterwards, and in some cases even in a few days, and in a very short time this is followed by unmistakable fading generally, while corresponding prints which were left unmounted have showed no evidence of deterioration. Under ordinary conditions, the natural inference would be that the cause of the evil rested with the mounting boards, and in every case we find it has really been attributed to them. However, a careful examination in one or two cases, at least, has shown that although the mounts could not be pronounced all that could be desired, perhaps, in the way of purity, still they did not contain anything like sufficient deleterious matter to account, *per se*, for the prints fading so rapidly as they did.

Having proved that in some cases the reason for the fading could not be assigned to the mounts, the next thing was to ascertain what was the mounting material that had been employed. This solved the apparent mystery. In every case it had been glue, and that, too, of the most unsuitable kind for mounting photographs. The different samples sent us, though not identical, were all of a very similar character, and had, probably, been selected on account of their pale colour and transparent appearance. The class of glue is that sold at different shops under different names, such as Cologne glue, refined glue, extra fine glue, &c. In general appearance it is intermediate between glue and a common gelatine, and it is usually met with in cakes or flakes somewhat smaller than those of ordinary gelatine, and is, we are told, usually of foreign manufacture. It is somewhat higher in price than Scotch or French glue of the better kinds.

When soaked in cold water, each of the samples (for they all behaved very much the same) swelled up nearly as much as a good gelatine would do, and communicated to the water a by no means pleasant odour, indicating that incipient decomposition had set up during its manufacture. They each made a very adhesive solution; indeed, for the purposes to

which glue is usually employed, it was of excellent quality. On testing the solution with litmus paper it proved to be strongly acid.

A solution, made to a consistence suitable for mounting purposes, after standing a day or two became thoroughly decomposed and liquefied, and gave off a very offensive smell. This would not have been the case with a moderately good gelatine. Notwithstanding the decomposition, the solution still retained the greater portion of its adhesive properties. In this state it is, of course, far easier to use, because it has lost its setting qualities, and for this reason, as we found, it was often preferred to a solution freshly prepared. One of the samples supplied by a correspondent was the mountant itself in the condition in which it is used, and it was then in a semi-liquid state from decomposition. Of course, when this kind of material is used for mounting even carefully fixed prints on pure mounts, it is not difficult to see why they should rapidly fade. But what shall be said if the prints themselves happen to be but imperfectly fixed or washed, and at the same time the mounts contain some deleterious matter? In such cases the extreme fugitiveness of some mounted prints over corresponding ones kept unmounted is easily accounted for.

It would be a libel on photographers, or professional photograph mounters, to suggest for a moment that they would employ any such material as that alluded to. Yet we find that it is often used by those who have no practical acquaintance with photography and its requirements. Stationers and others who sell photographic scraps, often purchase the prints—those produced abroad especially—unmounted and mount them themselves as their customers require. It is such as these who have brought the subject under our notice, and in every instance they have condemned the mounts as being the cause of the fugitiveness, or the prints themselves. The subject has proved an interesting one for inquiry, as we have found, strange as it may appear, that acid and decomposed glue or gelatine is by no means unfrequently employed for mounting photographs. As we have said before, it is easy to use, and the users are apparently ignorant of the pernicious effect it must necessarily exert upon the photograph.

Now, if this kind of thing exists to any great extent—and we sincerely trust it does not—it is easy to conceive how many reputations may suffer. For example, if the prints issued by such houses as those of Bedford, Frith, Wilson, Valentine, and others, who publish prints unmounted were mounted in a similar way to those just alluded to, they could scarcely be expected to fare, in the end, any better. Furthermore, the credit of the mount maker may also suffer, for the very general

assumption, when mounted photographs fade or become spotty while corresponding ones remain unchanged, is, and usually has been, that the mounts contain something which has wrought the mischief.

Gelatine, as we have often said, is one of the best mountants that can be employed for photographs, but, of course, it must be free from impurities, and also from decomposition at the time it is used.

SULPHITES IN CONJUNCTION WITH PYRO.

I.

IN response to several letters received since we wrote last week on *Pyrogallol Acid and its Preservation* we return to the subject, with a view of giving clear and explicit directions how to proceed in the matter of using the various preservatives in vogue, about which there appears to exist a good deal of uncertainty.

There is nothing at all ambiguous about the ordinary formula nor in the instructions given with regard to mixing, but a few words may be said on the subject of the usually accepted proportions of pyrogallol acid and sulphite of soda. These are one ounce of pyro to four of sulphite, and when used with a sufficient quantity of water to make a ten per cent. solution no better proportions could be adopted. But one thing must be borne in mind, namely, that it is not the proportion of sulphite to pyro that is of importance, but of sulphite to water. It appears that a certain strength of sulphite solution is needful in order to perform efficiently the duties of a preservative; it matters very little what is the strength per ounce of the pyrogallol, the sulphite should be nearly at the point of saturation, and then the solution will retain its powers as well as its freedom from colour for a very long period. Thus it will be noticed that though the stock ten per cent. solution of pyro with the corresponding proportion of sulphite will remain uncoloured, as we have said, for a lengthened period, as soon as it is diluted to developing strength it commences to oxidise and discolour, showing very clearly that when the strength of the sulphite is reduced it ceases to possess the power of protecting the pyro, though the relative proportions of the two remain unchanged.

It is important to remember this, because many operators have a fanciful way of mixing their developing solutions, being desirous apparently of acting differently from everybody else. Many individuals, for instance, of our acquaintance prefer to make their solutions not in concentrated or ten per cent. form, but just double the normal developing strength, so that by mixing equal parts the developer is ready for use. Apart from the inconvenience arising from the comparatively large bulk of solutions this entails, it is obvious that the strength of the sulphite is very far below the point of saturation, and that therefore its preservative power is very inferior, and, indeed, it is found necessary to constantly make the pyro solution fresh when required. The system, we admit, is a convenient one, but in working it it is necessary to keep the more concentrated solution as the "stock," to be diluted when needed for the working solution.

The standard strength of ten per cent. for the pyro has been selected from motives of convenience, and it may be made up with a cold saturated solution of sulphite, when the relative proportions of pyro and sulphite will be approximately 1:4. But if a stronger solution of pyro be preferred we must necessarily, though still adhering to the saturated solution, reduce

the proportion of the sulphite to pyro, and this may be done without in the slightest degree decreasing the keeping properties of the solution. On the other hand, if the strength of the stock pyro solution is to be lower than ten per cent., the sodium sulphite must still be kept as before, and consequently its proportion is increased relatively to that of pyro.

These considerations become of importance if, as many allege, sodium sulphite exercises a retarding influence on development, for obviously the smaller the quantity that will satisfactorily preserve the pyro the better will be the result, or, in other words, the more concentrated the stock solution of pyro, the less pronounced will be the ill effects, if any, of the sulphite.

We have, however, repeatedly expressed the opinion that no such retarding action exists in the case of pure sulphite, but that where it is observed it is due to the employment of a sample of that salt that has become largely converted into *sulphate*, or else to the over acidification with citric acid. Samples of sulphite vary very greatly, though they are, as a rule, much more uniform and of better quality than when the salt was first brought into general photographic use. The newly created demand apparently brought into the market a very inferior and unstable preparation, which frequently crumbled into a soft powder in a few days, even in a stoppered bottle. In strong contrast to these was a sample obtained by us from a pharmaceutical chemist, some ten years ago, for use in connexion with the hydrosulphite developer, and which remained unchanged up to two or three years ago, when we used up the last of it in testing it experimentally against a freshly made specimen. Recently the article supplied by photographic chemists has regained much of the old quality, and as a rule is to be relied upon.

Where this is the case no trouble whatever need be experienced in its use. All that is requisite is to make a hot saturated solution and allow it to cool, to render it very faintly acid, but *not* with *citric* acid, and to filter. We have a strong preference for sulphurous acid for this purpose, and it may be obtained in solution at almost any dispensing chemist's. The strongest solution obtainable has a specific gravity of about 1.045, and contains a little under ten per cent. of real acid, but the preparation obtainable at the ordinary chemist's is not likely to have that strength nor to be very uniform in quality. For the purpose of neutralising the free alkali contained in the sulphite its strength is immaterial, as litmus paper will save all troublesome calculations.

It has been shown by Admiral Mouchez (and in the *Annuaire du Bureau des Longitudes* a neat little engraving of the effect is given) how far removed from the simple operation it is usually supposed to be is the measurement of star distances upon photographic charts, and Dr. Pritchard made some observations upon the same subject at the British Association meeting. He showed that the image of a star produced under certain usual conditions consisted of a series of black dots, joined by intervals less dense. He found by experimental measurements that a bright star would be accurately represented on the plate if its image were, during the greater portion of the exposure, screened from acting upon the plate by the interposition of a stop of some kind.

Apropos of the subject of astronomical photography, it may be noted that it possesses one advantage of a very important nature over eye observations, in that the lenses of a telescope are free from the want of homogeneity of structure that distinguishes the lens of the human eye. Whatever the amplification obtained, be it small or large, the photographic plate records it accurately, while with the eye, unless

the magnification reach a certain limit, according to the focus of the object class, clear vision cannot be obtained, as rays of light would appear to be thrown out by the image, just as a bright star appears to do when viewed by the naked eye. Then, again, the extent of magnifying power that may be applied is, in the opposite direction, governed by the condition of the atmosphere. Unless the latter be very good, the highest magnifying power is unavailable; and the larger the telescope, the more frequent do such limitations interfere with its use, until with instruments on such a scale as the Lick telescope its greatest possibilities may not be utilised on more than a few nights in a year.

THE current number of *La Nature* contains an article upon dark rooms, which is illustrated by a number of neat engravings of furniture and apparatus. We have, first, a developing table showing an automatic rocker for plates; then a dark room lamp with transparent bottom allowing the light to fall upon a mirror which reflects it through the negative to the operator by the help of a dish made of clear glass. Under the notion that it is necessary to use a toning bath absolutely clear, and that the inexperienced operator would not be able to perform the operation of decanting with success, an arrangement is shown for doing this by mechanical means. The solution is contained in a jar fitted with a projecting neck at its lower part; into this neck is fitted a cork containing a glass tube bent at right angles. When the solution is not needed, the tube, which is movable, is fixed upright; but when it is desired to draw off some of the contents the tube is turned to a horizontal position, and the liquid flows out. It is in effect simply a cheap substitute for a glass tap. Finally, we have a washing trough for prints and a drying apparatus in which to suspend them, neither piece of apparatus possessing any features of novelty.

As the time is approaching when photo-micrography will again interest its votaries, we may here make a note of a method of treating polyzoa and other low forms of animal life to put them in a suitable state for being photographed. It is stated that by dropping a few crystals of chloral hydrate in water in which the polyps have been placed the creatures become insensible—narcotised in fact—and can then be placed in alcohol. It is claimed for this process that by its means the polyps may be retained as a specimen in a permanently expanded condition, by which means its full beauty of structure is exhibited.

How to blacken brasswork is a topic of perennial interest, and a query that we may always be sure of having put to us before the lapse of a long period of time. A correspondent of a scientific contemporary, writing from Chicago, repeats some old instructions, and states that the plan he recommends is superior to all others. His instructions are to dissolve a little copper wire in nitric acid, taking care to have the wire in excess; then dilute with water, apply to the brass with a brush, heat strongly until the nitrate turns black, wipe off and slightly oil.

MR. RAND. CAPRON, in his *Plea for the Rainband*, gives a full description of an instrument for weather foretelling which deserves a greater publicity than it yet appears to have had—Klinkerfue's weather compass. The compass is an ingenious combination of aneroid barometer, string hygrometer, and a wind scale, and gives its indications in a single reading, not requiring the collocation of a set of observations. The working arrangement is such that in dry-air conditions the hygrometer string acts with the aneroid for a rise, and in moist weather against it, the two instruments thus combining in a joint reading depending on the variation of each. Definite instructions for use are sent out with each instrument, with particulars for setting it according to the barometer or to the prevailing weather sign. The great sensitiveness to hygrometric changes is seen if the back of the instrument be breathed upon; the motion of the index may then be observed instantly. Such a handy little apparatus, particularly to the possessor of a pocket spectroscope, ought to be of real service in projected photographic expeditions.

For the purposes of the printer who makes his own chloride of gold, and desires first to obtain the pure metal, its precipitation from

solution of waste or of alloyed gold is generally recommended to be carried out by sulphate of iron, or sometimes by oxalic acid. In a recent number of the *Chemical News* the various methods of precipitation were examined, and preference given to processes of decided novelty. The writers, Herren Hoffman and Krüss, state that by means of sulphurous acid the gold is thrown down both quickly and thoroughly. The acid, in solution, is added to the dissolved gold, and the whole heated for half an hour; at the end of the time the gold is all precipitated, and can be filtered off without delay, a rapidity which is not permissible by the ordinary means, as any one who is familiar with the process well knows. There is also avoided all trouble in getting rid of iron as in precipitation with iron salts, and all loss by spitting which may take place when oxalic acid is used, though this latter is a loss more of interest to the analyst than the photographer.

THE greatest yield of gold was obtained when freshly precipitated oxide of mercury was used. The solution is mixed with the oxide, placed in a water bath, and heated, with the result that the gold precipitate collects in the very unusual form of a gelatinous mass.

LANTERN SLIDES ON GELATINE PLATES.

I.

A FEW weeks ago, in the *JOURNAL* for August 12, Mr. W. I. Chadwick, in the course of an article on *Stereoscopic Photography*, expresses the opinion that gelatine plates are unsuitable for lantern slides, and as he is an authority on the subject, it may be worth while to inquire if, and how far, he is correct in his allegation. I may at once say for my own part, that while I believe Mr. Chadwick may be in the main accurate, so far as he goes, I do not see any reason why gelatine plates should not make, I will not say as good slides as can be got with collodion, but at least as good as many that are so produced.

It will save trouble if I quote in full the charge Mr. Chadwick makes against gelatine plates, as I can then more readily analyse it and show where the faults lie. He says—page 504—"I will go so far as to say gelatino-bromide plates of *anybody's make* (commercial ones) are unsuited for making lantern slides; they are not clear enough or transparent enough without being hard, and if you do make them soft, they are veiled and flat, and, therefore, unsuited to the lantern." This statement is clear and explicit enough, and shows precisely what the author finds fault with in gelatine plates. Coming from such a source the condemnation is very severe, and may tend to prevent many amateurs, who might otherwise do so, from using gelatine plates for the purpose, their advantage over collodion in point of rapidity being so palpable that there are few who would not employ them if the results attainable were anything like equal to collodion.

I shall endeavour shortly to point out how and why gelatine plates do fail in the respects mentioned by Mr. Chadwick, and how it is the fault of circumstances rather than of necessity; and as the lantern slide season among amateurs is approaching, I shall show them how they may economise their time and opportunities by using gelatine instead of collodion, and at the same time produce results which, except in tone, perhaps, are little inferior.

This one advantage of rapidity is, perhaps, of greater importance in lantern slide making than those who have never worked that branch of photography would imagine. The work is usually performed at the worst time of the year for light, and the amateur's hours of recreation only, as a rule, permit him to use the worst of that or else artificial light; in either case, the gain in being able to use gelatine is most appreciable. As an example of the kind of exposures given with collodion emulsion plates, I may mention that a friend of mine, a well-known and successful worker of washed collodion emulsion, both for landscape and lantern work, used to adopt the practice of setting a plate to expose in the camera for the latter purpose before starting for business in the morning, and leaving it until he reached home in the evening. Of course, for contact work, the case is very different, but how few of our negatives are suitable for printing by contact!

Well, to turn to Mr. Chadwick's charges. In the first place, he

confines his strictures to commercial plates, and though there are several makers of gelatino-bromide who send out a special plate for lantern slides, I am bound to say that on the points mentioned by Mr. Chadwick none that I have tried can come up to collodion. This is from no want of care on the part of the manufacturer, nor is it from any want of capacity on the part of gelatine to give clearness and transparency in conjunction with softness, but it is rather, to my mind, the effect of working upon a commercial rather than upon a small scale. What I mean is, that where the very highest perfection is required, it is impossible, working on a commercial scale, to give that minute and, so to say, individual care to little matters that an amateur can who is working small quantities for his own use; it is on the same principle that the private tutor produces better results in special cases than class teaching. As regards the qualities of sensitiveness, and especially uniformity, no doubt the large maker has greatly the advantage of the amateur, but in the matter of mechanical perfection the latter, I think, has the best of it. Referring to this very point, one of our largest commercial plate makers remarked to me some years ago, "Your plates ought to be immaculate."

For a moment we will set on one side the chemical part of the question, and consider only the physical differences between collodion and gelatine. Take a film of plain collodion and one of gelatine of the strength ordinarily employed in emulsion, and compare the two. The collodion when dried upon glass exhibits to the eye not the slightest sign of its presence either by colour or structure. Under the microscope, no doubt, it does show a strongly marked structural character, but the power necessary is infinitely greater than any that is brought to bear by the lantern. Take the dried gelatine film, however, and it will be seen that though, perhaps, perfectly colourless in the extremely thin layer it presents, it is distinctly visible to the eye from the "varnish" sort of surface it possesses, and the innumerable, excessively minute specks formed in the film in drying, and resembling the pores of the skin. I am speaking of a layer of gelatine which has been dissolved in distilled water and filtered through filter paper, and not to one in which mechanical defects from dust and similar causes exist.

Such a film, when held before the eye, though it may possess no appreciable colour, and be practically as transparent as glass, produces the same effect upon objects seen through it that a poor quality of window glass does, and cannot, therefore, be an improvement to the definition of an image formed upon or in it. The intensity of the defect varies with different kinds of gelatine, and with the quantity used—the harder kinds, and especially those liable to the fault known as "pitting," being the worst offenders; but many of these are otherwise among the best that can be employed on account of their clearness and freedom from colour. The softer gelatines, and especially natural isinglass obtained direct from the dried swimming-bladder of the sturgeon, are the best in point of freedom from structure, but their slowness in setting and liability to frill and dissolve in development are great objections. The isinglass, too, possesses a peculiarity which can scarcely be looked upon as an advantage; the dried flakes, when placed to soak in water, exhibit a beautiful play of iridescent, nacreous colours like mother-of-pearl, and after solution, and when the jelly has set, these colours are transformed into a pale opaline tint almost fluorescent in its character.

This fault may be considered a purely mechanical one, but the next I shall mention partakes of a physico-chemical character, the result being produced by chemical means, though partly induced by the physical nature of the gelatine. Most, if not all, gelatines contain lime, either as an essential element in their composition or contracted in the process of manufacture. Some of the hardest and whitest samples are the worst in this respect, being very strongly contaminated with lime. So long, however, as the lime is present in a soluble form, its presence is of little moment, but as soon as it is converted into any of the insoluble forms, as oxide, carbonate, oxalate, citrate, or sulphate of calcium, it makes itself unpleasantly apparent by the opalescence it gives to the gelatine. When once transformed into the insoluble condition in the body of the gelatine, it is almost impossible to completely eliminate it; dilute hydrochloric or nitric acid will remove some of the opalescence, but not all, and here is one more cause of the diminished clearness and transparency of gelatine films.

Among the causes that may intensify this form of defect may be

mentioned contact with caustic or carbonated alkalies, which by separating the lime in the form of oxide or carbonate from the soluble calcium salt converts it into the objectionable form. In development, therefore, we may always expect to create a certain amount of opalescence if the gelatine be strongly charged with calcium salts, provided the precipitation has not occurred earlier, for another strong cause of this reduction is found in prolonged contact with ordinary spring or tap-water and its impurities. If the gelatine of which an emulsion is made contains soluble calcium salts and it be washed in ordinary water, the result will be a reaction in which those salts are rendered insoluble by the action of the carbonates and sulphates contained in the water, and, in addition, a further supply of lime and probably also of baryta is derived from the water itself.

With an emulsion made by the ordinary methods of boiling or digestion, the degree of opalescence thus created is not very great, and certainly not sufficient to injuriously affect the plates for negative purposes, though it mars the clearness of a lantern slide. But if we turn to an emulsion made with ammonia the case is far different, and the opalescence in that case may become a matter of serious objection, even in a negative; for under these circumstances the ammonia acts as a sort of trap for the lime contained in the washing water, throwing it down in the insoluble form in the mass of emulsion itself, and were it not that it is to a great extent soluble in the fixing bath, the deposit of lime thus obtained would entirely destroy the transparency of the negative. Some time ago, when experimenting with a formula in which a carbonate was used instead of ammonia for giving sensitiveness, I was so struck with this peculiarity that I tried to utilise it for the production of matt surface transparencies, to do away with the necessity for ground-glass.

It follows from what I have said, that the amateur who wishes to make gelatine plates that will be suitable for lantern slides, must most carefully select his gelatine in the first place, must free it from all mechanical faults by thorough filtration, and avoid using too thick a film, and so introducing other mechanical defects. He must also so arrange his methods of treating the emulsion, that as far as possible the deposition of insoluble lime in the gelatine is prevented, and the brightness and transparency of the emulsion retained intact. It is here that the amateur has the advantage over the large manufacturer, for he can, by using distilled water for every operation, or by utilising one or other of the precipitation processes of emulsification scarcely available on a commercial scale, avoid entirely the access of lime to the emulsion during the process of manufacture.

I now come to the last portion of Mr. Chadwick's charge, namely, that gelatine transparencies "are not clear enough or transparent enough without being hard, and if you do make them soft they are veiled and flat." I must say that such has not been my experience with gelatine plates, commercial or otherwise, that have been specially made for transparency purposes; but I am quite prepared to endorse it if Mr. Chadwick is referring, as I think he must be, to the ordinary commercial landscape plate. The fact is that if you want a gelatine plate that will make good transparencies, you must prepare it specially. It is not a debatable point, or a mere question of taste or opinion as in the case of slow *versus* rapid plates for general work, but it is a downright and incontrovertible fact that rapid plates from their very nature will not make clear and soft transparencies. The sensitive film is in such a delicate state of equilibrium that the exposure and development necessary to produce half tone and softness cannot stop short of veiling the shadows, the line of demarcation is too fine, the plate too delicate for the treatment. In fact, to obtain clear shadows you must under expose and so lose softness, or else sacrifice clearness to harmony, in either of which cases the result must be inferior.

How far those manufacturers who supply a special lantern plate modify their ordinary methods of working in their production I am unable to say, but I am convinced that by adopting every precaution and working carefully upon a small scale, a better result can be obtained than any I have yet met with; and I shall endeavour, in another article, to give clear working details, both as to formulæ and methods of treatment. Though, be it understood, I do not promise better results from gelatine than can be got with collodion, still in view of the immensely greater rapidity of gelatine, the amateur will find it conduce to his convenience to employ it in preference.

The emulsions I shall describe constitute what would be termed

"slow," when speaking of gelatine, though still many times more rapid than collodion, especially in a bad light; and they have this additional advantage, in virtue of their slowness, that they are easier to prepare and require fewer precautions than the more rapid forms, and hence may be attempted by those who have not hitherto taken up emulsion making.

W. B. BOLTON.

CAMERA MAKING IN JAPAN.

In considering what to write home from a foreign land, one can only assume that what has interested oneself will interest others. It is on this assumption that I write about camera making in Japan. I take, myself, a very great interest in observing the use of tools of almost any kind, and in noticing the difference in the method of use by different people; and as the manner in which the Japanese use many tools is totally different from anything I have been accustomed to see, it has been particularly interesting to me.

The excursion to the camera maker was made in the following circumstances. An officer of one of the American men-of-war in Jedo harbour, having called and introduced himself as an amateur photographer, mentioned that he was having a camera made by Japanese workmen. We decided to go to the workshop and see how the work was progressing, so we made our way to the Regent-street of Tokio—the "Shimbashi," I think it is called, but Japanese names will not stick in my head. Here was the dealer's shop. Most Japanese shops occupy the front part of the ground-floor—which is frequently the only floor, the houses being two storeys high at the most. The shop is separated from the street only by sliding shutters which are removed in the daytime, leaving the whole front quite open. The floor is raised about eighteen inches from the ground; it is covered with straw mats, the lighter wares are piled on it, others are stacked round the sides. On the mats sit (or rather "squat," as I described in a previous communication) the whole of the family, every member, as a rule, engaged in some kind of work, for the selling shop is generally the workshop, too, and what is to be sold is made on the premises. This particular shop is an exception, however—there is a workshop separate from it.

The dealer has a stock that would do very fair credit to a provincial dealer in England. He has a particularly good selection of lenses, amongst them a portrait lens, the largest but one that I have ever seen. It is only a six-inch lens, but the brasswork is disproportionately massive. It is of the old-fashioned, very long focus, and is, altogether, a colossal instrument. It is by a French maker quite unknown to me, and as the dealer wants 20*l.* for it, I fear it may be on his hands for a very long time. If, however, any English photographer has a desire to purchase it, I do not mind acting as his agent.

I first attempt to transact a little piece of business of my own. I have left the flange of one of my lenses in England. Has the dealer got one that will fit my lens, or will he make one? Our attempts to express this sentiment in Japanese—with much use of a vocabulary—result merely in "arimasen," uttered with great politeness. This means that he has not got what I want, and we are both equally incapable of explaining—even with the assistance of the vocabulary—that if he has not got one he might make one. We are relieved of our difficulty by one of the University students, who, passing at the time, consents to act as interpreter. The dealer says he can make a flange, but adds, with becoming modesty, that he will do it very badly, and that it will take him a fortnight to do. It has taken him more than a month, but I must say, to his credit, that he has made a very good flange. Moreover, he has charged only half-a-crown for his month's work.

The business in the store finished, we make our way to the workshop. It is on the first floor, up a flight of steps which are something between a ladder and a staircase, and which it would be remarkably easy to fall down.

The workshop is a room perhaps twenty feet square, the floor all covered with straw mats. We are accommodated with chairs. This is an unexpected and certainly a pleasant advantage. We had looked to sitting on the floor, and accommodating our lower limbs as best we could.

And now to give some idea of the manner of working, if possible. There are four carpenters in the shop; each squats on the floor with his bench—or what takes the place of the bench—and his smoking gear beside him.

The bench is nothing more than a flat board of hard wood, the dimensions some three or four feet long, about eighteen inches wide, and an inch thick. It lies directly on the straw mats. The smoking gear consists of a stoneware bowl, which is filled with wood ash, in the centre of which a few embers of charcoal are kept always alight. The bowl stands in a square box, in one corner of which also stands a

short piece of bamboo, into which is knocked the tobacco ash after smoking. The pipe has a wooden stem and a metal mouthpiece and bowl, the latter very diminutive. A pinch of tobacco is put into the bowl, the bowl is thrust amongst the live embers, a single puff, or at most two, are taken, the ash is knocked out of the pipe into the bamboo pot, and the smoke is over. The tobacco is the very mildest and is cut exceedingly fine. I think no Japanese workman is ever without this smoking gear. In his work he pauses every few minutes, takes his smoke as I have described very deliberately, then returns to his occupation. The smoke is by no means unpleasant, but would certainly be too mild to satisfy certain photographers at home that I could mention.

The bench has no arrangement whatever for fixing the work. It is merely the board of wood that I have described, without any addition whatever. That work should be turned out, on such a bench, of a quality to rival all but the very finest camera work at home, is a thing I certainly should not have believed unless I had seen it. One thing which enables a Japanese carpenter to get on without any arrangement for fixing his work is that he uses his feet as well as his hands.

It is doubtless mostly due to practice, but also in great measure to the foot-gear used by the Japanese, that they can use their toes to grip in a manner which Europeans could not imitate at all. The foot-gear consists either of straw sandals or wooden clogs—the latter generally mere thick slabs of hard wood—which are held on the feet each by a thick cord which passes up between the big toe and the one next to it, bifurcates just over the toes, and joins the sandal or clog again at each side of the heel. The foot is thus never cramped or distorted as with us, and the toes can be freely used. A Japanese tailor holds his cloth with his toes, and a carpenter holds and turns about his wood with his feet. I was about to say that he manipulated it, but this, I presume, would not be allowable.

The tools are much more simple than ours. The hammer is merely a cylindrical mass of iron with a transverse round hole through which the handle passes. The saw is merely a strip of steel with serrated edge, and with a "tang" whereby it is fixed into a round handle like a chisel handle, much as we fix a file at home. The work is done by the upward or drawing stroke.

The plane is, in general form, somewhat like ours, but the wooden portion is much thinner—shallower from top to bottom—and the knife is inserted much nearer one end than with us. It is unlike our planes in that there is no second adjustable iron, and that there is no wedge for fixing the iron. The iron is just in the form of a chisel, and is held in position by friction against the sides. With the plane, as with the saw, the work is done by pulling or drawing, not by pushing. The knife is fixed near the end which goes in advance as the plane is drawn along. One would suppose that with such a primitive tool only rough work could be done, but the very reverse is the case. I have seen a Japanese carpenter do what anyone who has ever practised carpentry will know is by no means an easy thing. I have seen him take out of the middle of a board of hard wood a thin, delicate shaving several feet long and the whole width of the plane iron. One reason, perhaps, why such good work is done with the Japanese plane is, that unless the edge of the knife is kept in very good condition the tool will not work at all. It is, therefore, kept as sharp as a razor, a deal of time being consumed in the very frequent setting of it.

One result of the simple construction of the Japanese plane is that a carpenter thinks nothing of making a special plane for any piece of moulding or such like work that he may have to do. These are sometimes very minute. I have seen them only about an inch and a half long, and three-eighths of an inch wide. It thus comes that much of the work done by us with gauges, chisels, &c., is done by the Japanese with the plane.

None of the other tools that I noticed differed greatly from those used at home, except in being rougher and less finished in appearance.

The work that was being done was merely the exact copying of an English camera and dark slides. At work of this kind the Japanese are very clever, but they appear to have but little capacity for original mechanical contrivance. They, moreover, have very little idea of saving labour by machinery, or of division of labour. The consequences are that, although they turn out work of the kind that I have been describing cheaply—the camera was to cost about one half what it would cost at home—they would turn it out no more cheaply if goods were manufactured on a large scale. If a thousand dark slides were to be made, each one would be made precisely as the first, one workman doing the whole of the work.

It is probably due to this very fact—to the fact that the Japanese use little or no machinery, and that, as a rule, an article is made from beginning to end by one individual—that we owe the indefinable

artistic charm which there is in the commonest product of Japanese labour. It is because each article has something of the individuality of the worker in it.

The camera maker thought it his duty to keep us entertained as we watched the progress of the work, and brought up to us, one at a time, what he considered the greatest treasures of his store. He brought first a fine and very large musical box. It was of French make, but set to play Japanese airs—or music rather, for I have failed as yet to find any approach to air or melody in the Japanese singing or playing. He next produced a Hall type-writer, afterwards various other mechanical toys for our amusement.

The bellows of the camera was being pressed in the selling shop by the simple expedient of piling lithographic stones on the top of it to a height of some four or five feet.

We are already here beginning to look forward to the eclipse, which will be total in great part of Japan. I hope to be at one of the observation stations, and to have something to tell English readers of what goes on.

W. K. BURTON.

HOW TO MANIPULATE THE CAMERA IN A MILITARY MANNER.

[A Communication to the Birkenhead Photographic Association.]

IN 1858 the dying embers of the Bourbon race as Kings of France were gradually fading out of view, caused by the rebrichtening lustre of Napoleon III.

Prince de Jonville published a pamphlet on the invasion of England. This was intended as a sop to the vanity of the French people, and a leaf out of the book of the First Napoleon. The only effect it had was to rouse the "nation of shopkeepers" to a sense of their insecurity. The British nation suddenly awoke, and their force of action was altogether independent of statesmen or legislators. Local corps of volunteers sprung up in every quarter of the country, calling upon Government to give them instruction in the use of instruments of war, and coupling it with a motto that "Defence, not Defiance" was their aim. "The Auxiliary Forces" have now taken root, existing for no less a period than thirty years, and may be said to be a permanent institution.

In the month of May, 1859, I became a member of the First Cheshire Volunteers, and underwent the process of drill, and in the course of a few weeks afterwards had the honour to present arms to the Queen and Prince Albert as they passed through Chester to the seat of the late Lord Penrhyn. I was then an ardent disciple of the colloid process. During the Crimean War in 1854, Government sent out Mr. Fenton to photograph the scenes of the war, and his pictures sent home gave a vivid idea of what a terrible thing war really was. For forty years peace had lulled us to a false repose, and the old veterans of the age of the First Napoleon with their experience had nearly died out. We found we had the men, but we had lost our Wellingtons and our Nelsons as leaders of a heroic band. In later periods, the Americans, during their war, made the camera do great and good work. Mr. Skaife, an enterprising inventor, about the same time brought out a Pistolgraph that gave pictures one inch square—enlargements were not much in vogue in those days—and after a short popularity it died amidst a galaxy of attractive novelties.

Military drill has two advantages in a photographic sense: firstly, its exercise of judging distances; secondly, rifle drill up to three hundred yards from the shoulder, and, after this distance, in kneeling position—thus giving a firm set to the body in process of firing. There are also considerable advantages in looking steady at the target before raising the rifle to the shoulder.

Now to carry this out photographically with the camera, having undergone the necessary drill, you must provide yourself with a "finder," which almost every amateur possesses, on the focussing glass of which you must draw lines in squares, so that each square will represent one square inch of the sensitive plate, keeping the centre object as the centre of the picture, having previously engraved on the flat rack of your camera the exact points of focus, say, up to thirty yards, for after that there is truly no focus. Lock the distance determined upon with the thumbscrew of the horizontal bar, uncover the dark slide, shoulder the camera, observe the focus of the finder and the relative size of the picture to the squares already described, and fire your Kershaw shutter, or any other of a light character, and the object is secured.

Rifle practice beyond three hundred yards is carried out by resting the body upon the heel of the right foot, with the elbow placed upon the left knee. This position is irksome at first, but perseverance will ultimately enable you to do it with ease and with the utmost promptitude. This position gives great rigidity and steadiness during the operation of exposure.

To obtain all the advantages of rifle practice, I fix the "butt" of the rifle to the under portion of the camera (through the ordinary stand screw); this beds itself into the shoulder, at the same time giving something for the hand to grip firmly, thus ensuring steadiness of aim, and does not require any alteration of the camera for general work.

It is almost unnecessary to state this plan ignores camera legs. The only additional article you require is an old rifle stock, which can be easily and quickly removed when required and placed in an outside pocket.

I would recommend camera drill as a health developer.

JAS. ALEX. FORREST.

PAPER WARFARE.

SINCE Mr. J. Gale's sorrowful lamentation (vol. xxx., page 4), that "with the ordinary silver printing on albumenised paper" he quite failed "to get the exquisite delicacies that make up the image on the negative," and his enunciation of the curious doctrine that "the beauty of the finished print is not proportionate to that of the finished negative," much has been done in the apparent endeavour to provide "a process," again quoting the hero of the famous "Swallows," "by which all the beauty and detail of the negative can be reproduced and retained in the finished print—a process by which we can print to the required depth and then stop, and tone to the desired colour and there finish off, without fear of the results of all our care and skill being rendered null and void in the after processes." This lamentation rent the air nearly five years ago. In the *interim*, platinotype, which not even the engineers of rival products will deny is "a process by which all the detail" (if not the beauty) "of the negative can be reproduced and retained in the finished print," has been skilfully lifted from the cold shade of neglect in which it then, comparatively speaking, languished, and manoeuvred into a commercial success. Now I think I am correct in saying that Mr. Gale's *forte* is landscape, for which the last mentioned process is, in the estimation of many, principally adapted; consequently Mr. Gale's opinion of platinotype in relation to his ideal process would be of peculiar interest. So also would Mr. Gale's present opinion of the aforesaid lament, seeing that despite such an emphatic expression of dissatisfaction with silver printing upon albumenised paper in January, 1883, he still patronises it, and presumably finds that it fulfils his purpose passing well, in 1887.

There are always a number of people about who are anxious to pull a thing down because it happens to be standing up. I select Mr. Gale's case at random, and, as the legal fraternity say, without prejudice. He is one of many who have made an Aunt Sally of an old and tried favourite without, happily, doing any damage. Albumenised paper has been with us for thirty years, and there have been almost as many revolutions (?) in contact printing. Estimating the probabilities of the future by past occurrences, I don't think these eccentric epidemics are yet stamped out—on the contrary, I fancy the malady is likely to take a more aggravated form in the near by-and-by. During the *lustrum* that has passed since Mr. Gale's lament, the burial service has been read over home and ready sensitised paper on an average once every three months by different celebrants, and still, to quote the bard, it rises Phoenix-like from the *sc*. Writing in strict chronological order, M. Hutinet's gelatino-chloride paper was one of the first to fling down the glove. This process gave exquisite results under a portrait negative, and it is a surprise to me that it has not survived. Then came an Acme paper, likewise an Alpha ditto—both, I believe, gelatino-chloride papers. Of the former we learned little, except that it precipitately swelled the bills of infant mortality, and the latter only survived till the summer time, when it gave up the ghost on account of a glut of sunshine in the meteorological market, and its inability to exist in any but an artificial light. It has recently been resuscitated, but with scarcely the success necessary to bolster up the prediction advanced at the first public demonstration of the process that it would pulverise poor old Albumen in double quick time. In the words of the dramatists, a year elapses and another revolution in contact printing surfaces occurs, for in the winter of 1884-5 (how odd it is that these revolutions generally take place in the winter!) an eminent firm gave us the fruition of their experiments in the shape of an excellent gelatino-chloride paper, whereupon the albumen *culte* began to look blue. To-day, however, the old horse is still travelling; whilst upon a cursory glance round the trade I do not find this particular new rapid, &c., on the market. Another interval of a year and film photography appeared, bringing in its train two or three gelatino-bromide papers; and at this moment others are *en route*. These papers are in little or no request for commercial portrait and landscape contact printing—in which connexion, be it understood, I wish my remarks to be considered.

Supplementary to these variations of the rusty device of coating paper with gelatino-chloride or bromide of silver for positive results, are Dr. Liesegang's collodio-chloride, and the late Herr Obernetter's gelatino-chloride, processes, both of which are popular in Germany, although they have only a handful of disciples over here. It will thus be seen that, commencing with the awe-inspiring platinotype and finishing with the Obernetter paper (the formula for which it is to be hoped is not buried with its regretted maker), albumenised paper has had a formidable lot to "take on," excluding from the reckoning many minor processes. It has come out of the conflict with credit, if not glory; it is still game; and, to conclude the allegory in the refined and courtly parlance of the ring, I think it worth standing against the field to a good sum.

Abandoning frivol and free metaphor, however, it requires little boldness to assert that from the point of view of public taste, sensitised albumenised is by far the most popular paper in commerce. Into its technical merits and demerits, and those of its competitors, I shall not go; that has been done thousands of times already by abler pens, while the entire subject of negative printing was incidentally submitted to a severe canvass in the course of the great permanency tournament held not long ago. I simply scan the matter from the platform of the disinterested critic. Yet, as what I am writing will to some appear mere froth unless flavoured with the essence of an opinion, I must confess that I rank myself among those stupid old fogeys who, if called upon to make a choice, think nothing can beat a good silver print; the sentiment of which, I hope, is plain, even though the language is a bit crusty. It seems to me that the motley tribe of new rapid, &c., papers depends for patronage entirely upon amateur workers. An intimate acquaintance with the economy of many studios supports me in the companion belief that professionals, and through them the paying public, eye them with scant favour. Good albumen prints boast an attribute dear to the heart of a discriminating sinner which neither the sacred platinotype nor gelatino-bromide possess, viz., richness and range of tone, in which respect the several introductions that have been going to sweep albumen off the face of the earth have shown, and continue to show, singular poverty.

On a former occasion, when the paper support for gelatine negative emulsion was heralded with such a blare of trumpets, I donned the prophet's mantle. My success has been so agreeable that I am induced to consult the stars once more, and predict a Methuselahic career for albumenised paper. It has most, but not much, to fear from platinotype, thanks, in a small degree, to protective restrictions and other causes. It should never be forgotten that the success of a photograph depends upon the quality of the negative and the skill of the printer, which, though a truism, gains rather than loses by repetition. There is no reason why the beauty of the finished print should not be proportionate to the beauty of the finished negative—no reason, that is, except the incapacity of the printer. I take it that while makers of ready sensitised paper are willing to guarantee its quality, they do not include a supply of brains at the same price. Perhaps that is the reason we have so many revolutions in contact printing. Who knows? What great events, &c. The wish, I suppose, being father to the thought, we are frequently assured that less sensitised albumenised paper is sold than heretofore. The reverse is the fact. Also constant reference is made to the jealously-guarded "secret" of the preservative employed. To paraphrase Mrs. Betsy Prig, "I don't believe there's no such thing." The real secret is that there is no secret, or, at least, not one of greater mystery than the right salt for the albumen, or the correct acidification after flotation on the nitrate bath.

There is an old saying that the public like warm and purple tones. Albumenised paper alone gives them satisfactorily. It is just as certain that professional workers have a decided preference for a printing out contact paper. In most of the new rapid series the image is developed up, which is a disadvantage, as anybody who can gauge the difficulties attendant upon the nice operation of exposure will allow. Just as in negative taking I regard magnesium, electricity, and every artificial illuminant as merely fanciful substitutes for the solar rays, so in regard to gaslight, lamplight, &c., for direct contact printing, I do not believe they will ever be treated other than as occasional makeshifts for daylight. You may deride the latter as you like, but it "whips" all artificial lights in point of cheapness and economy, and if not always available between sunrise and sunset in big towns, that is owing to our terrific consumption of coal, the bad effects from which the Smoke Abatement Society are going to obviate in due course, so that we may confidently look forward to beholding the apotheosis of poor, persecuted albumen within a measurable distance of time. The lately Japan-ed Mr. W. K. Burton was a staunch friend of albumen, and as I close this article I am reminded

of one from his pen that appeared in the last ALMANAC, wherein he remarks, *inter alia*, "It seems altogether impossible to get on without our old friend albumenised paper. Times out of number it has been decreed that he shall be banished the country, but still we have him with us, and I believe that in spite of its many rivals it is produced on a larger scale than it ever has been since it was first used." Very true; and I, if I may go a step further, believe that, taken as a body, photographers do not wish to "get on without him," and that unless the usual revolution in contact printing which will, of course, occur during the approaching winter eventuates differently to its numerous predecessors, they are not likely to make the attempt yet awhile. Naturally there is a moral to be culled from these depressing failures to oust albumenised paper from its pride of place. It is, Never be cocksure of anything. To many impulsive seers among us a retrospect of the dogmatic utterances of the past five years would be alike instructive and profitable. We have so often been fooled in the matter of these revolutions that when the next one is announced the revolutionary must not be surprised if the salt-box is in considerable request, and, what with scepticism on the one hand and icy indifference on the other, he finds himself between the devil and the deep sea.

MARSTON MOORE.

CHARTERHOUSE SCIENCE AND ART SCHOOLS AND LITERARY INSTITUTE.

THE Winter Session of this, one of the largest Science and Art Schools in the United Kingdom, will commence on Saturday, October 1, under the Presidency of the Rev. Henry Swann, M.A. During the late session about 950 students, mostly elementary teachers, availed themselves of the privileges afforded by this Institution, and of this number upwards of 650 presented themselves for examination and were successful in obtaining a large number of First Class Certificates and also a goodly number of First and Second Class Honors Certificates awarded by the Science and Art Department of South Kensington. Of eight students prepared for the Lond. B.Sc. (Int.) examination, only one student failed, the others highly distinguished themselves. Instruction of a practical character is given in most of the sciences at a very nominal fee; whilst in art at an equally low rate, students, under the direction of five competent instructors, can be advanced in their studies. Those who have leisure can at a very moderate charge attend the day classes in art. Day classes will also be held to prepare candidates for Matriculation (Lond.), the Clerical, Medical (including Dental), Legal, and other Exams. Students who aim at becoming proficient in Chemistry (organic and inorganic) have the opportunity of working in a well-fitted laboratory, capable of accommodating sixty students. Aspirants of University Honors can, at a small expense, be assisted in their studies. Classes for Matriculation, Latin, Greek, French, German, Music, and Shorthand, are taught by well qualified teachers. Opportunities for the study of Photography and Watch-making will be continued this session. Full particulars of the classes may be obtained from C. Smith, Organizing Secretary.

PHOTOGRAPHY IN NATURAL COLOURS.

FROM time to time notices appear in the daily newspapers announcing the discovery of a process for taking photographs in natural colours, and accompanied by editorial remarks about the march of civilisation and the gigantic strides of the human intellect in these modern times. Lately, both Cellerier's and Mayall's processes have received such recognition, but the methods of these two inventors only result in the production of pictures artificially coloured by the operator, and these colours are not produced by photographic action. The first observations on record in relation to photography in natural colours were made by Dr. Seebeck, of Jena, who wrote an article for Goethe's *Farbenlehre*, published in 1810, of which the following is a brief translation:—

"When I directed the spectrum of a faultless prism (so placed that the incident angle of the front became equal to the refracting angle of the back) on white chloride of silver spread upon paper and still wet, through an opening of about five to six lines in the shutter, and to the distance where the yellow just meets with blue, and kept it by a proper arrangement in this position from fifteen to twenty minutes, I found the chloride of silver changed as follows: It had become red-brown in the violet (occasionally more violet, at other times more blue), and this colouration reached also beyond the line of the violet designated before, but was not deeper than in the violet. In the blue of the spectrum the chloride of silver became true blue, and this colour decreasing and gradually getting lighter, extended into the green. In the yellow I found the chloride of silver mostly unchanged; sometimes it appeared to me more yellow than before; however, in the red, and often a little beyond the red, it had taken the red of a rose."

The early workers in photography, Niépce, Daguerre, and Fox Talbot, sometimes noticed local colouration in their photographs, and occasion-

ally of such a description as to give rise to belief that a tendency existed to reproduce natural colours. This mist began to clear away from this subject when it was taken up by Sir John Herschel, the first trained man of science who occupied himself with photography, and who discovered some of its laws and principles as accepted at the present day. He, like many other photographers, appears to have been unaware of the observations of Seebeck. In a letter to the British Association, dated Slough, August 28, 1839, and published in the *Athenæum* of September 21, 1839, Sir John Herschel said:—

"When a slip of sensitive paper is exposed to a highly concentrated spectrum, a picture of it is rapidly impressed on the paper—not merely in black, but in colours; a fact which I ascertained nearly two months ago, and which observation seems to have been alluded to (though in terms somewhat equivocal) by M. Arago, in his account of Daguerre's process. In order to understand what follows it will be necessary to describe the colours so depicted. The red is tolerably vivid, but is rather of a brick colour than a pure prismatic red. And what is remarkable, its termination falls materially short of the visible termination of the spectrum. The green is of a sombre metallic hue, the blue still more so, and rapidly passing into blackness. The yellow is deficient."

A few months later, in a paper contributed to the Royal Society, and read on February 20, 1840, Sir John Herschel went farther into details. He stated that he had been trying experiments to discover the influence of the solar spectrum upon photographic preparations, and in using a paper prepared upon principles laid down by Fox Talbot obtained indications of the photographing of colours; the paper, he said, was prepared with the following series of washes:—Firstly, nitrate of silver, s.g. = 1.096 (say 1:1); secondly, muriate of soda, 1 of salt + 19 of water; thirdly, nitrate of silver, s.g. 1.132 (say 1:15), saturating the muriatic solution with chloride of silver, and occasionally dividing the last application into two washes of equal strength by dilution. When throwing an intense spectrum upon this paper, the extreme and mean red rays impressed no colour, the orange rays a faint brick-red, the orange-yellow rays a brick-red pretty strong, the yellow rays red passing into green, the yellow-green rays dull bottle-green, the green rays dull bottle-green passing into bluish, the blue-green rays very sombre blue, passing into black, the blue rays black, and with long exposure a somewhat metallic yellow, the violet rays much the same as the blue rays, and the ultra-violet rays violet-black or purplish-black. He said that these results pointed in the direction of "the possible future production of naturally coloured photographic images." After another experiment with a more perfect and intense spectrum, he said that the paper was coloured with "sombre but unequivocal tints, imitating those of the spectrum itself." The papers could not be fixed, but could be half fixed by washing in water; the colours also deepened a little within the first few days after the photograph had been taken. His conclusion that these hues bore reference to the possible production of natural colours by photography was not generally accepted at the time, and Biot forthwith argued that the taking of photographs in natural colours was of necessity an impossibility.

In 1841 Robert Hunt stated, in the first edition of his work entitled *Researches on Light*, that fluoride of silver had a tendency to reproduce the colours of the spectrum. He says of one of his photographs, then two months old: "A yellow line distinctly marks the space occupied by the yellow ray, and a green band the space of the green; through the blue and indigo region the colour is an intense blue, and over the violet a ruddy brown."

In the next step, photography in natural colours reached much firmer ground. Edmond Becquerel, in a communication to the French Academy of Sciences, dated February 7, 1848, called attention to the experiments of Seebeck and Herschel, and stated that he himself had found that the effects were best obtained with well-washed chloride of silver mixed with a little gum in order to distribute it over paper, and he thought that the nitrate of silver in excess used by Sir John Herschel interfered with the results. Becquerel discovered that if the argentic chloride film were first exposed to weak diffused light until it became of a faint violet colour, and were then submitted to the action of the spectrum, it took on a well-marked blue in the blue rays, and a rose colour in the red; in the yellow it was bleached, and the same film gave a beautiful blue, with no trace of violet, under glass. This encouraged Becquerel to additional research. He placed a polished plate of silver in chlorine water for several minutes, until it took a white tint, and when exposed to the action of the spectrum it reproduced the colours thereof, but not quite in the positions where the particular colours fell upon the plate. The orange came out well, and the green near the D line of the spectrum; the red had a purplish hue, the green was well marked near F, where the photographic impression began to pass into blue, the violet appeared near G and extended to about H. With longer exposure the colours grew deeper, but after an hour or two of exposure the colours disappeared, and the whole image took a metallic lustre. He found it difficult to prepare these plates with an even film; several short immersions gave the best results, and the plate was at its best when it assumed a faint rose colour. Becquerel then tried other ways of preparing the plates, and in one of them substituted cupric chloride for chlorine water, but finally obtained his best results by connecting the plate with the positive pole of a battery, and throwing down chlorine upon it from a weak solution of hydrochloric acid. The plates gave colours beyond the limits of the visible spectrum, and Becquerel remarked that it would be

necessary to get rid of or to absorb such rays in attempting to take photographs in natural colours in the camera. In trying to print coloured designs from paper upon his sensitive plates, he could photograph only some of the colours. He came to the conclusion that the film upon his plates was not pure chloride of silver, but a mixture of chloride and subchloride, and supported this view by means of chemical tests. He was, however, unable to fix his coloured photographs. They appeared to keep well in the dark, but were destroyed by the action of light. His first memoir on the subject containing the foregoing particulars was published in the *Annales de Chimie et de Physique*, Third Series; vol. xxii. Paris, 1848. In another memoir published in the *Annales de Chimie*, 1849, vol. xxv., Becquerel states that after trying cupric and other chlorides, also various hypochlorites, he found that nothing gave him better results than throwing down nascent chlorine upon the plate by voltaic action in water acidulated with hydrochloric acid. Although in these different ways only chloride of silver is formed, the films produced are not acted upon in like manner by light. For instance, the film obtained in very dilute cupric chloride gives a white colour under the influence of white light, but it will not give all the colours of the spectrum. To prepare a plate of about twenty-five square centimetres, the current from two feeble charged Bunsen's cells is used; the solution consists of 125 cubic centimetres of hydrochloric acid to each litre of distilled water. The surface of the plate is made chemically clean before immersion. A platinum plate is connected with the negative pole of the battery. The operation should be carried on in a place feebly lighted. First the surface of the silver turns grey, then in succession yellow, bluish, and green; then grey, rose, and violet; then blue a second time; and the operation has to be stopped just before the second blue stage is reached. The plate is then washed with distilled water, and dried above an alcohol flame. When thus prepared, it should have a violet colour. The total time of immersion in the hydrochloric acid bath should not be more than one minute, during which it may be taken out from time to time to see if the right stage has been reached. After preparation the plate will keep well in darkness. Becquerel's solar spectrum was formed by means of a lens of fifty centimetres focus, and was four or five centimetres long. The colours obtained upon the plates were sombre, the blues and violets coming out best. He found that he could improve the results by heating the prepared plate over an alcohol flame in a dimly lighted room before exposure to the spectrum, at a temperature of about 100° C. The operation must be stopped when the plate acquires a roseate hue. It will now give a positive instead of a negative impression, and the colours of the spectrum appear now more brilliantly. When a large spectrum is used, the time of exposure may be one or two hours, and Becquerel found that he could improve the results by pre-exposing the film to light behind a trough filled with sulphate of quinine placed in the path of the rays. He still failed, however, to fix his coloured photographs. Under coloured glasses they took the colours of the glasses, and in the usual photographic fixing solutions the colours disappeared.

Niépce de St. Victor brought, in 1851, his experiments upon heliochromy under the notice of the Paris Academy of Sciences. In his memoir he states that there is a relation between the colour produced by a salt of chlorine in a flame, and the colour produced upon a silver plate on which the chlorine has been thrown down from a solution of the same salt. Thus, a plate prepared in a solution of chlorine and chloride of strontium will show the reds better than any other colour. For orange, he used uranium or calcium as a base; for yellow, sodium; for green, nickel; and so on. Chloride of antimony or zinc, he says, gives a white flame, and if one of these salts be mixed with chlorides which give colours, "we obtain, in addition, a white ground, a thing very difficult to obtain, because, properly speaking, there exists no black or white in the phenomena of colouration." The zinc salt has to be used in minute proportion, or it hinders the production of the other colours. He states that chloride of copper in an alcohol flame exhibits not only the green, but all the other colours of the spectrum in succession, according to the intensity of the flame. Hence this salt is useful in reproducing all colours. He prepared some of his plates with equal parts of chloride of copper and perchloride of iron, dissolved in three-fourths their weight of water. Sometimes he prepared plates from a solution of a large number of chlorides, but found it difficult to mix them in the right proportions, so that they should give photographs with natural colours in their true relation to each other. He mentions the names of a great number of chlorides with which he experimented, but gives little or nothing in the shape of exact formulæ, and he found that it was much more easy to photograph brilliant than subdued colours. After dressing a doll in fabrics of selected colours, trimmed with gold and silver galleon, he photographed it and obtained the colours successfully, the gold, instead of being dead yellow, coming out in the picture with its natural metallic lustre. Niépce found that when a plate was used directly after being taken out of the bath and dried an invisible copy of a coloured picture could be made, and the colours afterwards brought into view by gently rubbing the film with cotton wool dipped in ammonia; this dissolved the outside film, and revealed the colours upon the silver plate below. In one of his papers to the Academy of Sciences he says plainly that he is reserving information as to his exact method of working. He says that he found the presence of dextrine to be useful in obtaining natural colours upon chloride of silver. The facts of the case appear to be that Niépce took up Becquerel's discoveries, and by dint of practice turned out better photographs in colour by them than

had previously been seen. As to the quality of the results obtained by these heliochromic processes, Niépce has according to general testimony been most successful. Some of his earliest photographs in colour were sent to the *Athenæum* newspaper, which spoke very highly of them.

Niépce's results were fairly durable. About ten years ago the writer saw one of Niépce's photographs of the spectrum, belonging to Mr. Warren de la Rue, purchased by him at the first Exhibition in Hyde Park in 1851. He kept it in a leather case, which he occasionally opened for a few moments to show the photograph to those interested. Every one would at once recognise it as a good coloured image of the spectrum, but slightly sombre in appearance. About a year ago, in a letter written from Homburg, Mr. de la Rue informed the writer that the photograph was still in as good condition as when first purchased by him. Ammonia, applied at a carefully regulated strength, seems to be the most successful of the partial fixing agents of heliochromic pictures.

Work more original in its nature was subsequently done by Poitevin, and communicated by him to the Academy of Sciences, as published in the *Comptes Rendus* for 1865. He sets forth that he had found oxidising agents to improve the action of the violet subchloride of silver, and that if paper coated with it were then treated with bichromate of potash, it displayed more colour sensitiveness. Poitevin took paper coated with pure chloride of silver, and turned it into the violet chloride by exposing it to feeble light while covered with a reducing agent, which Becquerel in another place says was usually protochloride of tin. Poitevin then applied to its surface a mixture of one part of a saturated solution of bichromate of potash, one part of a saturated solution of sulphate of copper, and one part of a five per cent. solution of chloride of potassium. The paper when dry will keep for several days. The function of the chloride of potassium is to keep the whites clean. This paper would to some extent give natural colours, when paintings upon glass were placed upon it, and the exposure to light then made. It was, however, not sensitive enough for the camera. To fix these images, the prints were washed in water acidulated with chromic acid, followed by water containing bichloride of mercury, then by a solution of nitrate of lead, and lastly by pure water. They would then resist the action of ordinary light fairly well, but would turn brown in direct sunlight.

The next and final stage of importance in research in relation to heliochromy was made by M. de Saint-Florent, and is published in the *Bulletin de la Société Française de Photographie* for 1873. A sheet of paper of very fine grain is steeped in nitrate of silver twenty parts, distilled water twenty parts, to which is added, after solution, alcohol one hundred parts, and nitric acid ten parts. The paper when dry is soaked in hydrochloric acid fifty parts, alcohol fifty parts, and nitrate of uranium one part. A few grammes of zinc white are dissolved in hydrochloric acid before the mixture is made. The paper is exposed while still wet to solar light until it assumes a violet-blue colour. It is then dried and plunged afresh into the nitrate bath, then in the hydrochloric acid bath, and dried as before between the two immersions. The foregoing operations are repeated until a very intense violet-blue is obtained, that being the only way of afterwards obtaining vigorous proofs. The paper is nearly dried, then put into a bath of water one hundred parts, acid nitrate of mercury four or five drops, and allowed to remain therein for five or ten minutes, then dried with blotting-paper. It is next exposed under coloured glass—say a magic-lantern picture—to the light of the sun, and in thirty or forty seconds a proof is obtained of all the colours of the design. The colours are more vivid, and the rapidity quite as great, if the following be added to the preceding mercury bath: Saturated solution of bichromate of potash or ammonia two parts, sulphuric acid two parts, chloride of potash one part. It will be noticed that Saint-Florent treated his violet chloride of silver with strong oxidising agents. To fix the pictures to some extent they are washed in a large quantity of water, then plunged into ammonia five parts, and alcohol one hundred parts; they are again washed in water, and then placed in a saturated bath of alkaline chloride. After a final washing they will resist for a long time the action of diffused light. Greater rapidity is obtained if the darkening of the chloride of silver be effected under violet or blue glass. To produce camera pictures by this process, exposures of from fifteen minutes to one hour are necessary with a Dariolet lens of 0.20 m. focal length, and with its largest diaphragm, the object being illuminated by direct sunlight.

Saint-Florent's theory of his process is that when paper covered with subchloride of silver, with excess of hydrochloric acid, is plunged into a bath of nitrate of mercury, it becomes impregnated with Hg_2Cl , which, under the action of solar light, is reduced to Hg_2Cl , or calomel. The freed chlorine transforms the violet chloride into white chloride, and afterwards the proof consists of coloured subchloride of divers tints, white chloride, calomel, and Hg_2Cl in excess. The last is washed out by water or alcohol. The calomel may be removed, he says, by transforming it into the higher chloride, either by means of aqua regia or chlorine water; then the white chloride of silver is gently removed by weak ammonia and alkaline chlorides, without attacking the colours. The usual photographic fixing agents do not answer.

Since Saint-Florent's experiments research in this subject has made little advance. On the coloured chlorides of silver recently made in bulk by Mr. Carey Lea, only the blue and violet colours have been obtained by him under the action of the spectrum; he succeeded a little better when he used coloured glasses. Captain Abney, in his article on *Photography* in the *Encyclopedia Britannica*, states that he has done something

on the subject, as recorded in the *Proc. Royal Society* for 1880, but the reference is an erroneous one.

In conclusion, the considerable advance made in the production of photographs in natural colours seems to have been effected mostly by empirical methods. One of the most interesting points in the results achieved is the photographing of metals and certain gems so that they give their own lustre instead of dead colours in the pictures. The hues of mother-of-pearl have also been photographed. Had a method of fixing the photographs been found out a great impetus would have been given to research, and it is evident that if the final deposit upon the plate is some combination containing silver and chlorine the picture cannot be permanent when subjected for a long period to light. The chlorine in the future must be removed, either with or without the substitution of another substance, and the film must still be left in such a condition that it will act in the same manner upon the rays of incident light, so as to still yield the colours of thin plates. Although for convenience the term "subchloride of silver" is always used in considering this subject, it should not be forgotten that it is a disputed point among chemists whether subchloride of silver has ever been isolated or not, although claims to have produced it have been frequently advanced, even down to the last few weeks.

W. H. HARRISON.

—Industries.

HOW ANGERER PHOTOGRAPHED AN INTERIOR.

L'Amateur Photographe contains the following narrative, which it quotes from "*Ind. photog.*," whatever that may mean:—

All who have to photograph interiors know the difficulty there is in obtaining good results when the lens exactly faces a window; they also know how they disquiet themselves about probable results in the shape of halation, and how good prints may possibly be unobtainable in spite of the most skilful retouching. Up to this time the plan of gumming red tissue-paper over the window has been adopted, but the results have been second-rate. In revenge, here is a process by which such interiors facing the sky can be photographed without solarisation, and at the same time the perspective view outside the window can be reproduced perfectly. It is the plan recently adopted by M. Victor Angerer.

This celebrated Viennese operator had to photograph a *salon* in Rothschild's palace. Independently of the difficulty imported by contrasts between the colours of the hangings, the furniture, and so on, another condition complicated the operation. The lens faced two windows in a circular wall, both admitting daylight. One of the windows was directly in front of the lens, and through it could be seen the church of Saint Charles.

M. Angerer solved the problem of producing his negative without solarisation, and beheld how:—

He focussed perfectly in full light, then he pasted black paper over the troublesome window, and he closed the second or lateral one by means of a double curtain, which permitted but little light to enter. The other windows in the *salon* gave the necessary light, but M. Angerer pasted white tissue-paper over them to diffuse it. He then exposed in the camera a dry plate for "a day and a half," after having placed a minute stop in the lens. At the end of this time he supposed the plate to be over exposed, and he capped the lens. He then opened the curtains of the lateral window in the circular wall, after which he gave another exposure, but of fifteen seconds only, the same plate being still in the camera. He again capped the lens, and removed the paper from the front window, then he exposed the same plate once more, but for four seconds only. The effect was surprising. There was no trace of solarisation, all was perfectly harmonious, and a special charm was given to the photograph by a sharply reproduced view of the church of Saint Charles outside the embarrassing window.

PERMANENT INTENSIFICATION WITH MERCURY.

The first point that suggests itself in connexion with the subject of the intensification of negatives, is the question whether they should ever require intensifying at all. Some practitioners say that they should not, and that in their own experience they never find any necessity for intensifying a negative subsequent to the development. It has also been said that a negative which has been intensified is never so good as one which has been developed to the proper intensity in the first instance.

Taking the last proposition first, I can see no reason why intensified negatives should be of necessity inferior, nor as a matter of fact have I found them to be so. Certainly if the negative is originally veiled in the shadows, and so requires intensifying in order that it may be made to yield prints showing some brightness, that negative will never be equal to one that was originally clear. Intensification, however, must not be blamed for faults which it did not create, because it is employed as far as possible to remedy them. On the other hand, reasons may be given why under certain circumstances a better result may be obtained by leaving the negative somewhat thin in development, and afterwards intensifying it, than would be possible by getting up printing intensity during the development itself.

When gelatine emulsion plates first displaced collodion for general

studio work in England it was remarked by a gentleman whose opportunities for forming a judgment were certainly exceptional, that the change of practice was accompanied by a marked deterioration in the quality of the negatives generally produced by photographers. One of the principal defects at that time, and I think it is still the weak point in a large number of cases, was a certain flatness in the lights due to a want of discrimination or separation in the sensitive film of different degrees of light; a want, that is to say, of power to register various degrees in the more strongly lighted portions of the plate. The forehead and light side of the face, for instance, may come with sufficient force to print as light as they should do; but the higher points of light on the nose, forehead, &c., will not show a proportionate increase of density such as will cause them to show their true value as we see them, or as they may be seen with other conditions of the chemicals.

This state of things exists in some degree to a very large extent. It is not noticed so much as it should be, because the retoucher's pencil is constantly called in to add these sparkling lights which give so much truthfulness, beauty, and value, to a photograph. It must be admitted, however, that it would be far better to have this registration of high lights rendered by photography itself, and, indeed, when it is left to the retoucher, the truthfulness of the rendering becomes open to considerable question, and must depend upon the individual ability of the retoucher himself.

When the want of sparkling intensity in the highest lights is due to an insufficient amount of silver in the film, as from too thin a coating, or if it proceed from any incapacity of the particular film to take sufficient intensity to build up these highest lights, it is obvious that an attempt to gain sufficient general intensity while developing, that is to say, with the material actually existing in the film itself, will result in bringing up the lighter half tones to about the same intensity as the highest lights, and thus produce the flat effect which has been spoken of. If, however, in such a case we are contented with a comparatively thin image in development we may, with management, succeed in producing an image which, although insufficiently vigorous, yet possesses a range of tone in which the highest lights may be seen distinctly marked out from the lighter half tones. Such a negative subsequently intensified will give a much finer print than one which, under the conditions given, owes all its intensity to the development.

In addition to the cases where a better forced negative may be obtained by keeping the image somewhat thin in development, and intensifying it afterwards, than by forced development alone, there are those frequently occurring where, from over exposure or other causes, a sufficient amount of intensity cannot be obtained in the development itself. Moreover, when there is no difficulty in obtaining intensity there is an uncertainty to most people. I confess there is to me in the light of the dark room and whilst the plate is charged with an undefined amount of silver bromide, varying with the thickness of the coating, in deciding upon the exact amount of intensity at the development stage. A good method of intensifying is, therefore, a very desirable and very useful adjunct to our other photographic operations.

Without going over the details of other methods of intensifying, I will describe the one which I have employed now for some years and which I use, I may say, every day. It certainly succeeds better in my hands than any other that I have tried, and friends to whom I recommended it speak of it in equally high terms.

One of the intensifying processes of the collodion days consisted in the use of a solution of bichloride of mercury, followed after thorough washing by one of Schlippe's salt, sulphantimoniate of soda. This process will, with certain precautions, succeed with gelatine negatives, but the colour obtained is very red, and it is consequently difficult to judge of the intensity, and inconvenient to the retoucher. I much prefer, and regularly use, a solution of iodide of mercury followed by Schlippe's salt. To prepare the iodide of mercury, take a certain quantity of saturated solution of bichloride of mercury. It is convenient to keep always a bottle of this saturated solution, and as it is used from to put in more water, and when need be, more crystals of the bichloride. Pour off enough of the saturated solution to one quart; fill a pint bottle—a wide-mouthed empty pyro bottle answers capitally. Now put in a few crystals of iodide of potassium, and keep the solution swilling round the bottle. The crystals very quickly dissolve and more may be added whilst keeping the solution in a continual swilling motion until the red precipitate first formed is redissolved. If it be thought that a considerable excess of iodide has been added, more bichloride solution may be poured in, until a little red precipitate is again just formed. This may or may not be redissolved by another crystal or two of iodide. I have not found that a slight excess of either of the ingredients interferes with the action of the solution. We have now a strong solution of iodide of mercury, which, for very weak negatives, may be used as it is, but it is generally better to dilute it two or three times with water before use.

The negative to be intensified must, of course, be thoroughly fixed, and have the hypo washed out of it in the usual way before the mercurial solution is applied. This may be done either in a dish, certainly the best method for large sizes, or poured upon the negative held in the hand. The latter plan affords opportunity for specially strengthening particular portions of the negative, as, for example, one face in a group. To do this the solution may be poured from a lipped measure on to the spot where intensity is most wanted, and allowed slowly to spread over the

rest of the plate, which may then be rapidly washed and the process repeated if need be.

If the mercurial solution be used in a dish, the latter must be kept in motion, otherwise peculiar wavy or arborescent markings may be formed. If these marks have started, they may be got rid of by allowing the negative to gain full intensity all over, and if then too dense, it may be reduced after washing by a short stay in the hypo bath before treatment with the Schlippe's salt.

A point to which attention must be given is the thorough removal of the mercury solution by washing, before applying the Schlippe. If this is not done, a yellow stain will be formed which will slow the printing considerably and probably show stains from inequality. I have found, however, that half an hour in an upright washing trough, after a good rinse under the tap, is sufficient, although, of course, with a very thick film of gelatine more time might be required. After washing, examine the negative in a good light to decide whether the intensity is right, bearing in mind that the next process, whilst fixing the intensity, will also somewhat add to it. If deemed too dense, it may, as before mentioned, be reduced in the hypo bath before Schlippe, but not afterwards. The hypo bath for this purpose should not be one that has been much used for fixing and become highly charged with silver. When an old bath of this character has been employed, I have even known the intensity of a negative to be increased, instead of diminished by it, and this intensity at the same time fixed, as if by the Schlippe's salt. I have thought of working out a formula by which such a bath might be used in the place of the Schlippe with which it is my habit to finish.

With a new and moderately strong hypo bath, the intensity given by iodide of mercury may be removed to any extent desired. If this operation has been performed, the plate must be washed again in the usual way before the final operation, which consists simply in pouring on a solution of Schlippe's salt—strength immaterial, say, five or ten grains to the ounce of water—until the characteristic change of colour is seen at the back of the plate. A final washing concludes the process.

If it is judged even now that the negative is not intense enough, the whole process may be repeated, but I prefer in this case to use a bichloride of mercury bath instead of an iodide of mercury one for the repetition of the process. If bichloride of mercury solution be used, however, it must, as pointed out by Mr. Arnold Spiller, be rendered slightly acid with a drop or two of hydrochloric acid, otherwise a combination is formed between the gelatine and the mercury. After washing, the Schlippe is to be repeated and the plate finished by washing, as before.

It is a point of great importance with this, as with all other intensifying processes, that the plate should be thoroughly fixed. It is a well-recognised fact that there is a silver compound in a gelatine plate, which takes longer to dissolve in the hypo than the visible bromide of silver does, and it is, therefore, a rule with many, and a good rule too, to leave a plate in the hypo for about twice as long a time as it takes to make it appear fixed to the eye. If any of this undissolved silver compound be left in the film, it may generally be recognised after the application of the mercury as a sort of bloom which shows from the back of the plate, and which looks as if it were between the plate and the film. If a plate in this condition is treated with Schlippe's salt, this bloom will develop into a deep orange stain. When it is present, therefore, the negative should be placed in strong, fresh hypo until the bloom disappears, when it may be washed and treated *de novo* with mercury-iodide solution, for the intensity given by the first application will all have disappeared in the hypo, and the plate will be indeed somewhat weaker than at the start.

Of course, there should never be a yellow stain due to imperfect washing between the application of the mercury and of the Schlippe's salt solutions, but if it should occur, it may be much modified by the application (after thorough washing, of course) of the acidified solution of bichloride of mercury which has been before referred to. In this case, however, Schlippe's salt should not be used again, but the plate should be merely washed and dried.

The use of Schlippe's salt I have found advantageous, not only for rendering mercurial intensification permanent, but also for restoring printing vignon to plates that have been treated with mercury and afterwards faded. In this case I thoroughly remove the varnish with alcohol, and after soaking in water, flood with a solution of the salt, and then wash again.

W. E. DEBENHAM.

—*Photographic Times.*

ON THE TREATMENT OF VERY SENSITIVE PLATES.

[American Convention.]

Dry plates were originally made to take the place of wet plates, with hardly a thought of making them more rapid than collodion, and the keeping quality was at that time the main desideratum. That the dry plate contained within itself the possibilities of great speed was evolved at a later day, and as the working of dry plates became more familiar to the craft, a demand for more speed or sensitiveness was made, and as promptly met by emulsion makers, and plates are made of sufficient sensitiveness to reproduce objects moving at a high rate of speed, and really wonderful achievements in this direction are to be seen every day. That plates of a high degree of sensitiveness require very careful treatment is at once apparent when we consider how readily they respond to the

faintest touch of light, be it light entering through the lens or through a pinhole in the bellows of the camera (which may be invisible from the outside), the minutest ray of light entering through door of slide, or between tablet and back of camera—prolific sources of trouble. All of these will be promptly registered upon the plate, causing fog, for which the plate will often be blamed and condemned as foggy and worthless.

Although very sensitive plates are as easy to manipulate as plates of lower sensitiveness, they require more care and attention to have the proper safeguards thrown around them—safeguards which really should be used for all dry plates. It is not fair to subject plates of different degrees of sensitiveness to the same conditions and treatment to determine upon their merits. For reasons already stated, a slower plate may remain perfectly clear when a more sensitive plate will show signs of fog in the same proportion as when an old style wet plate would be compared with a modern dry plate. It is a pity that so often the finest plates are spoiled by improper treatment.

If photographers would be all as careful in their manipulations as the maker of the plate has to be, there would be little complaint, and it would not happen that one will say, "No. So-and-so is no good." Another will write, mentioning same number, "Send me every plate you have of it." Another one writes, "I want a very rapid plate, but one that is not so sensitive." This is an absurdity; rapidity and sensitiveness are one and the same, and cannot be separated.

To work very sensitive plates successfully, everything should be in the best working order. The dark room, aside from being roomy, well ventilated, and having all the necessary conveniences, should be perfectly tight, and the colour of it, inside, non-actinic. Coloured paper used for the lantern or window will fade, and should be removed from time to time. Examine dark room, camera, tablets, and lens at intervals; see that your dishes are always clean and everything convenient. Have your chemicals fresh and pure and well stoppered. Bear in mind the difference between chemicals of the same kind but in different form. For instance, sulphite of soda granular is about twice as strong as sulphite of soda crystals. Carbonate of potassium is about equal in strength to dried carbonate of soda; both are about twice as strong as the carbonate of soda crystals or sal soda, as it is commonly called.

Guard against any trace of diffused light, too much exposure to the coloured light while developing, or having the coloured light too strong. Use fresh developer for short exposures and old developer for over-timed plates, remembering that old developer will produce more contrast and clearness on addition of a little old developer or a little bromide developer in proportions to suit the exposure. If very much over timed, restrain by adding solution of bromide of potassium, and if under timed dilute the developer, and do not try to force the development by adding an extra dose of alkaline solution, as this will only injure the plate.

Observe that a developer strong in pyro produces strong negatives, and that the temperature of the developer and the quantity of alkali it contains is of great importance. If the developer is warm or contains too much alkaline, it will fog a very sensitive plate. Keep the developer cool in summer (about 70° Fahr.); in summer the strength of alkali should be reduced to one-half the strength used in winter.

If uncertain about correctness of exposure, start with developer diluted with plenty of water, so that you may see what the plate wants before it is too late. If you commence with a strong developer the image will flash up at once, and the negative may be spoiled before anything can be done to save it. If you commence with diluted developer you have a chance to change or modify the developer as the plate requires it.

There are many points in developing to which a careful operator will give due attention, and the results will demonstrate that it is worth all the labour and study to thoroughly master the science of development.

G. CRAMER.

KILLED BY OVERDOSE.

[American Convention.]

THE uses and abuses of developing methods in general practice is my subject. I give my impression and my opinion more as an observer than as a handler. I do not expect to tell you anything new, but may attract your attention to my impressions in a manner to get some value, if any be in them. The formation of the image in the negative plate and the positive paper are operations of such importance that we can hardly learn too much about them.

First let us consider the negative. You all know that pyro is the developing agent (I say pyro, because it is almost universal in this country), and that the accelerator, whether it be ammonia, soda, or potash, is the power that sets the pyro at work. You understand that the pyro produces the intensity in lights or the white parts of your image, and that the accelerator takes care of the dark parts by working up the lower shadows and giving detail and modelling through the lesser ones.

You all have your formulae, which you believe in. It is not my purpose to disapprove of any one, but to caution you to a careful use of all.

The exposed plate has an image in it; possibly the image is a landscape, some parts of which lie in full light, while another part falls in deep shadow, or a clump of heavy, dark foliage occupies the foreground—perhaps it is a room interior, which was dimly lighted, or the portrait of a

person taken much in shadow. We are about to call that image into a palpable existence—to make a visible fact of it. In case of either of the above described exposures shall we take the usual formula of proportion—so much No. 1, so much No. 2, to so much water—as printed directions to be found in every package of plates says is proper?

Dare we do it? I say no, if we care to find the best results. Now is just the time to go slow, the image can be better coaxed than driven. Take time, be patient, and get your reward. Understand you cannot get your density first and your details afterwards, but *can* first get your details and afterwards your density. It is always best to first lay the foundation and then erect the structure. Any builder will tell you that.

One of the most valuable elements of a developer is water, and it is too little used, or, in other words, too little of it is used.

Particularly for all plates of suspected under exposure or of doubtful time, as well as for all large heads, a weak developer is required to start, and if found to want more strength it is easily changed by addition of pyro.

Looking to pyro for density and the accelerator for details, it is easy to understand by varying the proportions of these two elements most any desired effect can be secured. The strong developer gives dense, harsh results, while a weak developer gives soft and delicate effects, hence the value of more water. Remember the mild power is most effective for perfect results in developing. Don't give heroic treatment at the start in any case.

It often happens at the close of a day's work, with a big crop of negatives to develop, that the operator, anxious for supper, pushes the work too rapidly for safety. The next morning they are found coarse, harsh, and smudgy. They were killed from overdose. If the proprietor have a care of the good name of his work the sitters must be recalled and retaken. Too much haste often spoils what a little patience would have saved. What I believe to be the best and safest method is to commence with the developer weak and with the accelerator in excess of the pyro. As the development progresses, and a want of more strength or density is discovered, pyro should be added to it. To wear the same weight of clothing throughout the year, in cold and hot weather alike in a climate like ours, would be reckless and inhuman, but no more absurd than to give all plates the same strength of developer. No man can give a formula for all plates and all conditions, but by care and observation all men who develop plates may learn to adapt proportion and strength of solution to the plate requirement.

Now a word about making the image in the albumen paper. All printers know that silver makes the print—too many of them think the more silver used the better the print. As a rule, when anything is found to be wrong more silver is doused as a remedy. Where forty grains of silver to the ounce of water is recommended by the albumeniser of the paper, who knows the proportion of salt used and bases the requirements of silver upon that knowledge, the usual printer requires sixty grains. Just enough chemicals for plate or paper is better than too much. The tendency to overdose is prevalent, and the results are similar upon plate and paper alike. In both cases the overdose gives harsh effects, forms a crust upon the surface, preventing the gradual and perfect conversion through the film—clogs the shadows and flattens the lights. It is not unusual to see prints with the shadows and dark parts hardly loaded with a bronzed Mars, and sometimes even a green fog from overdose. Gold is always subject to the same abuse, being sometimes used so strong as to destroy rather than produce good tones.

A little more knowledge among operators and printers of paper, and necessary conditions for successful work in their departments of photography, and a careful observance of the requirements, would greatly lessen the mortality list in plates and paper.

J. F. RYDEN.

OBSERVATIONS AND COMPARISONS.

[American Convention.]

WHILE it is not my motive to give a lengthy paper on this subject, I shall only refer to Germany, France, and England, as compared to home photography, trusting that it will be of value to you, especially to our younger members who are deeply interested in their profession. It has been often said that European cities, with their well-stocked art galleries and museums, which contain the choicest art treasures that have been concentrated during centuries, create large influence in the art training of the student photographer. This advantage you have often referred to in former Conventions of the Photographers' Association of America, that our foreign photographers enjoy. During my tour in Europe I visited their celebrated art galleries by the score. I walked along walls covered with canvas for miles, representing all the old masters, paintings large and small, the majority representing sorrow and subjugation. How shall we employ these studies in photography in this advanced nineteenth century, when it is our endeavour to represent in our work life and joy?

But does the photographer take advantage of such object-lessons his Government has so beautifully placed at their disposal? Upon inquiry I was told, and my observations agree, that the art galleries and museums are the abode of tourists. Then what advantage have they in the race for progress over us? Compare their miles of canvas and marble to the miles of photographs you have been enabled to study through this Association, and the thousands of object-lessons here placed before you.

For a number of years several German photographers favoured our Association with their best work, which received our universal admiration, but how about the average of work in Germany compared to America? Large cities like Berlin, Dresden, and Frankfort contain several very fine studios, where good work is done; the same is true of New York, Boston, and this city—Chicago. If we compare their elegance and conveniences, sizes of cameras, &c., and the amount of large work done, they must take a back seat.

The studios in Berlin, while several are in Unter den Linden and main business centres, they are situated in the rear of the main line of buildings, the entrance is through a passage into an open court, where the studio is generally on top of a three- or four-storey building, accessible by narrow stairs, while others more favourable have built their studios in a garden; but the latter are often in the outskirts of the city and hard to find. Skylights in Berlin are very large, and some have a length of forty to fifty feet. But while the studios are so unfavourably situated, the photographer displays his work along the public squares and other places accessible to them. Some have erected elegant pavilions for their display, and those contain booths for the sale of opera tickets and for making appointments for sittings. Such a novelty might be introduced here. The number of galleries in Berlin, Dresden, and Frankfort are not so numerous as in New York alone. Photographers of small means and poor workmen seldom locate in large cities, but remain in small towns, or tramp through the country. Prices obtained here for cabinets range from ten to thirty marks, and orders from quarter to half dozen are the rule, but the cabinet has not obtained public favour, for the *carte-de-visite* still holds the fort; prints above ten and thirteen are the exception, and the majority of photographers have not even the instruments to fill an order. There is another individual I must not overlook, for I know you are all anxious to hear from him. The Cheap John, he has his abode there, too; but, unlike our American Cheap Johns, he is not so numerous nor so well up in photographic branches yet, for he is a very poor copy of his American relations. I noticed a fellow who had his place on one of the principal streets in Berlin, and over his shop, a very small one indeed, he displayed the now famous large white rag of distress, "*Amerikanischer schnell photographie, a ein mark!*" Now you will be as astonished when I tell you that this American quack photographer was our old and long-forgotten ambrotype on glass, and backed with asphaltum. If he had used ferrotype plates, it would have been proper to term them American.

JOSHUA SMITH.

(To be continued.)

THE ROYAL CORNWALL POLYTECHNIC SOCIETY'S EXHIBITION.

(By a Special Correspondent.)

THE Fifty-fifth Annual Exhibition of the Royal Cornwall Polytechnic Society opened at Falmouth on Tuesday, September 6, at eleven o'clock a.m. The opening ceremony took place at one o'clock; Lord Robartes, the President, presided, and gave the opening address. On the platform were Lord Robartes, Mr. A. Pendarves and Lady Jane Vivian, Rev. Canon and Mrs. Phillpotts, Sir Warrington Smyth, Mr. Talbot Baker, Mr. Edward Vivian, the Hon. Mrs. Boscawen, Major Parkyn (Hon. Sec. Royal Institution of Cornwall), Colonel Bull, Colonel Pender, Revs. Canon Rogers, W. Rogers, H. M. Jeffrey, F.R.S., W. N. Caine, W. Brooks; Miss A. M. Fox (the founder of the Royal Cornwall Polytechnic), R. Carter (the Mayor of Falmouth) and Mrs. Carter, R. N. Worth, F.G.S., R. Fox, H. Fox, Mr. E. Kitto, F.M.S., Secretary, &c.

Lord Robartes, in his address as President, said that he thought this year's Exhibition would compare favourably with its predecessors of former years, and it gave him great pleasure in seeing so distinguished a company present. He then alluded to the various departments, viz., Mechanics, Naval Architecture, China Clay Works, Engineering, Natural History, Fine Arts, Gas, &c. He said that the new patent Welsback incandescence gas must not be overlooked, as it was one of the features of the Exhibition; it gave a very brilliant and steady light, without flame or smoke, and thought it had a great future before it. He said that the Photographic Department was considered the best that had ever been, which was under the direction of Mr. W. Brooks, who took great interest in the Society. Among the exhibits were some very fine specimens of the art. Mr. J. Byrne, of Richmond, was awarded the first silver medal for a very beautiful untouched portrait of the Hon. Frederick Tollemache, Mr. Lafayette receiving the second silver medal for the portrait of the Countess of Londonderry, which was very fine indeed. Mr. H. P. Robinson had a very beautiful composition picture—a pastoral subject, with great artistic merit; he again was awarded the first silver medal. Mr. W. H. Hyslop received the only award for his most perfect studies of yachts racing, in the amateur section, a second silver medal. Mr. B. Wyles, of Southport, had a marvellous specimen of instantaneous photography—a flight of sea gulls, which was very interesting; this also received an award. Mr. W. Brooks lent a frame of beautiful lantern transparencies of Windsor Castle State Apartments, &c. This department was the most perfect in the Exhibition. He had to acknowledge gratefully his obligations for valuable information in the various departments to Mr. Worth, Mr. Davidson, Mr. Brooks, and Mr. Kitto, the Secretary.

At the end of the address he proposed an address be presented to Her Majesty in this her Jubilee year. They might appear somewhat late in the day, but their meeting had only just taken place, and it was not practicable to arrange it before. The proposed address was then read.

The Society had had Her Majesty for its Patron ever since 1836.

Mr. Pendarves Vivian, in a very brilliant speech, seconded the proposed address, which was received with great applause and enthusiasm.

Several other speeches followed by Sir Warrington Smyth, F.R.S., Talbot Baker, Esq., and several others, and the usual vote of thanks was given to the President, Lord Robartes, and the Exhibition was declared open.

At night the photographic department was illuminated by the Welsbeck Incandescence Gas Company, which was a perfect success. This light, in all probability, could be used for photographic purposes, as by its colour it is probably very rich in actinic rays, and well worth a trial.

THE ART UNION OF CORNWALL.

The Annual Drawing of the Art Union Prizes took place on Friday evening, in the Polytechnic Hall. After the drawing the winners select prizes to value from the works of professional artists that are for sale in the Fine Art Department, and also from the works of professional photographers which are marked in the catalogue for sale.

The following are the winning numbers with prizes:—

1244 Mr. Job	£0 5	1380 P. D. Williams	£1 0
1215 Mrs. Babling	3 0	779 B. Freeman	3 0
625 Robt. Fox	2 0	894 Earl of Mt. Edgecumbe	0 5
1394 G. R. Bossistow	2 0	1057 E. Carter	2 0
666 W. N. Carne	1 0	1329 E. Williams	1 0
411 Mrs. Genn	2 0	436 A. W. Tuer	10 0
404 H. W. Broad	1 0	1026 W. Kneebone	2 0
1458 Rev. R. C. Sowell	5 0	1117 A. H. Best	3 0
596 Earl of Mt. Edgecumbe	0 5	563 Lord St. Levan	0 5
1251 Miss M. P. Sharpe	1 0		

PHOTOGRAPHIC DEPARTMENT.

Judges Report.

The Judges in this department again have great pleasure in congratulating the Society on the great superiority of the Exhibition in this department over preceding years. In portraits the exhibits are above the average in number and also in quality, many of the specimens are of large dimensions, and far surpass anything that has hitherto been exhibited; there are some life-size examples taken direct. In landscapes by professional photographers, the exhibits are, perhaps, not quite up to the number of previous years, but the examples are of the highest order.

In instantaneous photography there are some marvellous examples of birds on the wing, &c. In composition pictures there are some very clever and artistic productions. In the amateur section there are some perfect gems of photography and quite on a par with many of the professional productions, which speaks well for their energy. In specimens of interiors little or nothing is exhibited. In the photographic appliance department there is a falling off.

PROFESSIONAL SECTION.

No. 602, a study of trees, by J. Milman Brown (an old exhibitor), possesses artistic merit and is highly commended by the Judges. No. 590, *Landscape and River Scene at Derwentwater*, by Mr. T. A. Green, has been awarded the first silver medal as the best landscape in the Exhibition; it is printed in platinotype and is a most artistic production, and of a kind that is seldom seen—the atmospheric effect is extremely fine. The same gentleman has several other exhibits which are well worthy of notice. No. 609 is an instantaneous picture of a large number of sea gulls on the wing, and this has been awarded a second silver medal. The birds are in every conceivable position, and most of them perfectly sharp, showing that the exposure must have been very rapid, and such a picture must prove of great value to the painter. This picture is by Mr. B. Wyles, of Southport. The same exhibitor has several other meritorious productions.

Mr. George Jones contributes a very amusing picture of some dogs, also several cloud studies; the latter, in the opinion of the Judges, are printed a little too deeply to be effective. No. 617, *Carolling*, by Mr. H. P. Robinson, is a most artistic production, and must rank among that gentleman's works as one of the finest; it is full of poetry, and is printed in sepia, and too much cannot be said in its praise. As usual, he takes the highest award—the Society's first silver medal. Mr. E. T. Shelton sends a very good enlargement, *The Morning Tub*—a little child about to take its bath.

Mr. J. B. Scott sends several artistic productions. Mr. J. Weir has several fairly good pictures. Mr. W. J. Byrne, of Richmond, sends some very high-class work. A first silver medal has been awarded to a direct picture of large size of the Hon. Frederick Tollemache. It is a most splendid specimen of untouched photography, the finest in the Exhibition. The frame above it, by the same artist, contains some specimens of photography (portrait studies) taken in ordinary rooms, &c., being perfect gems in their way, and cannot fail to attract attention.

Mr. W. Crooke contributes some enlargements in platinotype, which are very effective.

Mr. A. G. Gibson, of Penzance, sends some of his well-known studies; the most striking is a picture of two Newlyn fishwomen. A second silver medal has been awarded to a picture of the Countess of Londonderry, by Mr. J. Lafayette, of Dublin. It is a perfect picture, and the retoucher's art has played a prominent part. There are several other magnificent works of the same order. Messrs. Werner & Son send some very fine portrait studies well worthy of notice. Mr. J. Geddes sends two pictures; *The Blacksmith*, a composition picture, is admirable. Messrs. West & Son again send some of their yacht pictures, which are wonderful productions, but the Judges do not think they quite come up to their former exhibits.

Mr. W. Winter, of Derby, again sends some of his well-known work. Mr. Luke Berry is represented by some clever studies. No. 666, *Preparing for Boxing Night*, composition picture by Mr. F. Whaley, is a picture of great merit, being an interior. The figures quite carry out the idea of what they are intended to represent, and the accessories are well in keeping. To this picture has been awarded a special first bronze medal. The same exhibitor has several other high-class productions. Mr. W. P. Marsh contributes several examples varied in character, and very artistically treated. Messrs. Johnson Bros., of Henley-on-Thames, have some good examples of instantaneous photography of Henley Regatta, which are perfect in their way; they have also two enlargements which are good. Mr. T. G. Whaite sends some very high-class portrait studies well worthy of careful inspection. Mr. John Pike shows some good specimens of careful work. Mr. R. W. Robinson contributes a number of small pictures which are very artistic, but rather too small to tell well at an exhibition.

Mr. Warwick Brookes, of Manchester, receives a first bronze medal for his frame of direct portraits, life-size, No. 708, which are very effective. Mr. W. England, of London, sends some small instantaneous pictures taken on a tricycle, which are very perfect and natural. Messrs. Morgan & Kidd have been awarded the medal for enlargements, viz., first bronze.

AMATEUR SECTION.

The Reredos, All Saints', Stoke Newington, a picture by Dr. E. W. Alabone, has been awarded a first bronze medal. It is a very elaborate piece of work, and is well rendered, being full of exquisite detail. The same exhibitor has several river scenes. These are somewhat heavy through under exposure, and the sky parts being all white tends to make them hard; with more exposure and a suitable sky printed in they would make capital pictures, as the subjects are well chosen. F. M. Puddicombe, R.N., also sends some well selected scenes, but several of them are somewhat heavy; the defect seems mostly due to the printing. The same exhibitor has a well defined flash of lightning, which is very curious. The best pictures in this department are Mr. W. H. Hyslop's yachting studies. He has some of large size, and appear to be the best examples of yachts in the Exhibition, and he seems to be a little in advance of the professionals in this special branch; they are very soft and delicate and with good atmospheric effect. Mr. F. K. Hurman sends several good studies. Mr. A. J. Leeson also has a nice little picture. Mr. W. J. A. Grant this year is very varied in his selection, which is an advantage; his Irish cabin is a beautiful little picture. He has also several well chosen subjects with figures, but the best of his exhibits are two frames of portraits taken in a drawing-room, and are finer than many taken in a studio. A first bronze medal has been awarded to Frame 748. The figures are very artistically posed, and the rendering of the drapery is perfection. Mr. W. Clement Williams sends a selection of outdoor pictures, which show great taste and skill. The Rev. H. B. Hare takes the landscape prize this year, a first bronze medal for a capital picture, *Thirsty Moments*—a meadow and river with cattle. It is a charming little picture, and is very soft and at the same time brilliant, with sufficient force and vigour. Mr. George Davison has some clever little sketches, mostly figure subjects, some of which are very comical, but each one tells its own tale. To the picture *Coal Heavers* has been awarded a second bronze medal. The same gentleman has also several rural pictures which show great talent and artistic taste. Mr. H. D. Crocker, R.N., sends several clever river studies, which show careful manipulation. Mr. R. Hansford Worth contributes several outdoor groups, which show good manipulation; the groups are well arranged and have a very natural effect. *The Deverstone* is a pleasing little picture, but if a suitable sky had been printed it would have greatly improved it.

PHOTOGRAPHIC APPLIANCES.

No. 800, a photographic print washer of an improved form. The Judges have given it a good practical test, and with a moderate pressure of water it works well and is very effective. The prints are kept in gentle motion and can be drained at the finish. A second bronze medal has been awarded to it.

A MEMORANDUM ON THE POWER OF DISCRIMINATING MINUTE SPACES.

NOTING the effect of different sized apertures in the production of an image on the focussing screen of the camera, it occurred to me how small an aperture, in a good light, would it be possible to see with unaided vision. Much of course depends on the eyesight and how

the space is illuminated. The smallest visible aperture I can call to mind is a pinhole in a negative which is made visible chiefly by irradiation, but it would be impossible to estimate its size without an instrument.

The following plan of estimating the diameter of a small space, although perhaps of no practical use, is curious as showing the exceedingly minute spaces that can be appreciated by ordinary and unaided eyesight. If a pinhole $\frac{1}{16}$ of an inch in diameter be made in a piece of metal foil (this is easily done by setting off $\frac{1}{16}$ inch on a similar piece of foil and pricking in it twenty holes close together and so large that the twenty in a line will fill up the space of $\frac{1}{16}$ inch). Holding this up to the light (the eye being protected from any other than that passing through the aperture) and steadily looking at it with one eye at such a distance that the edge of the hole is a little out of focus, there will appear a network filling up the space consisting of rings (I counted nine distinctly and several not so distinct), which do not overlap in any part but quite fill up the aperture, and consist of an opaque circle enclosing a space, the line forming the circle being about a sixth of the diameter of the space. Knowing that the pinhole is $\frac{1}{16}$ of an inch in diameter, and that four of these rings are required to fill a line across it, they would be each $\frac{1}{64}$ of an inch in length, the lines forming the rings being but a sixth of their diameter. The thickness of these would be $\frac{1}{1024}$ inch. The triangular spaces formed between the outside of the rings were apparently about half the diameter of the lines, but indistinct. Therefore in a rough estimate we might say that a space of $\frac{1}{1024}$ of an inch is appreciable by the unassisted vision.

EDWARD DUNMORE.

Our Editorial Table.

LEISK'S SKY SHUTTER.

THIS shutter, which is manufactured and sold by Marion & Co., Soho-square, is one of the rotating class. The aperture in the rotating and exposing disc is so devised as to give an exposure to the foreground of about three times the duration of that given to the sky, by which are secured those cloud effects which impart such a charm to a landscape. Its formation will be seen from the adjoining illustration.

The shutter is made of ebonite—very light, and can be adjusted to any length of exposure, from about one-fiftieth part of a second to any length desired. It is fitted with Cadett's Patent Pneumatic Release, and this, together with the construction of the shutter, which reduces friction to the minimum, prevents vibration during exposure.

IMPROVEMENTS IN WASHING AND DRAINING RACKS FOR PHOTOGRAPHIC NEGATIVES.

No. 4202. GEORGE FREDERICK BLACKMORE, 1, Coulter-road, The Grove, Hammersmith, W.—March 21, 1887.

IN arranging the sides and ends of racks with hinged connexions in such a way that they form a parallel or nearly parallel motion when being folded, collapsed, or closed up, and in making either or both of the sides partly or wholly detachable at will, for greater convenience in folding or closing them up.

To carry out my invention I arrange the parts in such a manner that the rack can be quickly prepared for the reception of negatives or similar articles, and may also be rapidly closed or folded up into a very small space, thus making it extremely portable and convenient for packing or stowing away for travelling. The rack in its simplest form is made of two sides of corrugated or grooved zinc or other suitable material, the corrugations or grooves being of any number according to the quantity of plates or negatives that it is intended to hold. The two corrugated or grooved sides are maintained when in use at suitable distances apart, corresponding to the size of plate or negative that it is to be used for, by two or more bands of wire or strips arranged so as to pass at right angles to the corrugated or grooved sides in a continuous length along the backs of them and to connect them at the ends.

To the outside of the corrugated or grooved sides the wire bands are attached at suitable distances apart, and parallel to each other in such a way that they form a hinge or parallel motion. By this arrangement the sides may be moved so as to lie end to end and perfectly flat. Along the inside of the corrugated or grooved sides, at a suitable distance from the bottom, is fastened a strip of wire or other material to form a stop or ledge on which the negatives or plates can rest, and which prevents them passing through the rack when being used. To the upper of the parallel wires or strips there are attached two or more loops or handles that are free to turn on the wires, so that when necessary the rack can be suspended by them, and when not in use they can be folded down close to the corrugated or grooved sides.

In some cases I arrange a number of the corrugated or grooved sides in a row and connect them all by a series of wire bands or parallel motions, so that they will all fold together when required.

I sometimes arrange two or more pairs of parallel strips or wires to connect the corrugated or grooved sides, without passing along their backs, by means of loose pins or rivets at each end of each strip, so as to afford a hinge or parallel movement similar to that already described.

In other cases I so arrange the parallel wires or strips that either or both of the corrugated or grooved sides can be partly or wholly detached from them, and thus allow the rack to be folded into a still smaller compass. This I accomplish by means of hinged or spring clips or their equivalent fastened to the corrugated or grooved sides by means of pins or rivets, or by soldering or equivalent method, so that they can clip the wire bands or be detached when required, and allow the corrugated or grooved sides to turn or hinge freely, as previously described.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

ON Thursday night, September 8, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. W. H. Prestwich presided.

The Hon. Secretary exhibited a print of a flash of lightning taken by Messrs. Robinson & Sons, of Regent-street, London. Like the one previously exhibited by Mr. Gray, in one part of its course the flash apparently turned back upon itself in a loop. A print of a Convention group by Mr. Crooke, of Edinburgh, was also exhibited.

Mr. A. COWAN, in support of a contention of his that bromide of potassium is not a restrainer in the developer when an alkali is present, said that he had developed several similarly exposed negatives with solutions containing different proportions of the bromide, the maximum used being sixteen grains to the ounce. The plate in the latter was the longest in developing, but gave more detail and a more brilliant picture than did any of the others: he concluded that the bromide retarded but did not restrain development. Mr. Warnerke, he stated, once exhibited a splendid picture from a plate which had had eight times the proper exposure upon an edifice in Moscow; the plate had been soaked for half an hour in bromide of potassium before development.

Mr. B. WOLLASTON stated that citrate of soda was a powerful retarder. Mr. W. M. ASHMAN said that Mr. Watmough Webster had first published the latter fact; he used a one per cent. solution.

Mr. A. HADDON remarked that when pyrogallol was preserved with citric

acid the subsequent addition of ammonia necessarily caused the formation of the powerful restrainer, citrate of ammonia.

Mr. COWAN added that anyhow such use of citric acid acted very well practically.

A question in the box was, what would remove the yellowness of negatives reduced with ferridcyanide of potassium.

Mr. ASHMAN responded that a weak solution of hydrochloric acid removed it at once.

Mr. COWAN preferred very weak perchloride of iron as a reducer.

Another question in the box was, what was the best material for lens mounts to reduce their weight for tourists, and should photographic societies weigh all lenses exhibited at their meetings and publish the figures obtained.

Mr. WOLLASTON did not see why the mounts should not be made of aluminium.

Mr. COWAN said that as aluminium did for opera glasses he did not see why it would not do for photographic lenses.

Mr. F. A. BRIDGE remarked that there was much difference in the weight of brass in lens mounts; the foreign mounts were usually very heavy. Much of the weight was in the tubes; the tubes perhaps could be made of aluminium, even if the cells were of brass.

Mr. HADDON thought that the flange should not be so near one end of the lens as at present, but be near the diaphragm slot, so as to reduce the vibration when using a shutter.

Mr. COWAN surmised that perhaps the maker would think that that plan would make the lens look smaller and not big enough for the money.

Mr. Plomer exhibited a photograph, said to be of a rainbow, taken by a friend of his when on board ship off the coast of Australia. One broad, nearly straight, shaded band crossed the picture from top to bottom.

The members generally expressed the opinion that a rope or metal bar out of focus near the lens had been photographed, and that the rainbow did not appear in the picture at all.

Mr. J. B. B. WELLINGTON had once photographed a rainbow; it made a very faint impression upon the plate.

Mr. J. J. BRIGNSHAW once obtained a broad band like that in the print before them upon a series of paper negatives, and had been unable to discover the cause of the phenomenon.

A few remarks were then made about the liability of insufficiently fixed paper negatives to darken all over by keeping, and the necessity for using a strong hypo solution when fixing negatives upon paper.

Mr. WOLLASTON knew of some beautiful bromide opal plates in the market which it was impossible to fix with a very strong solution of hypo.

Mr. ASHMAN had received Mr. Burbank's new book from America, and had carefully read it through; it professed only to be a compilation, but that compilation had been very well done, so that it was a practically useful book of reference. Had any one noticed the remarkable falling off in the actinic power of the light that afternoon? He had found it at least twelve times slower than usual at the same time of day.

Mr. BRIDGE had noticed it and found it to be about fifteen times slower than usual.

Mr. WOLLASTON had found at Chislehurst, a few miles out of London, that at twelve o'clock that day plates required double their usual exposure.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

At the meeting held at Myddelton Hall, Islington, N., on Tuesday, September 6, Mr. J. Traill Taylor, President, in the chair, Mr. Arthur E. Smith was elected a member of the Society.

A question was asked whether there was any advantage or disadvantage in constructing a doublet lens with the combinations of widely dissimilar focus.

The PRESIDENT said that rectilinear lenses were now frequently constructed with the back combination of shorter focus than the front, this system being found to conduce to flatness of field.

Mr. J. JACKSON had been in the habit of interchanging the combinations of his portable symmetricals, and found that he could obtain lenses of intermediate focus which worked thoroughly well.

The HON. SECRETARY in using his Darlot's combination set preferred to use a long focus front combination with a short focus back combination.

In opening the discussion on "Lantern matters," Mr. A. MACKIE said that when using a condenser, either for enlarging or for projecting a picture on the screen, it had been recognised as a principle that the source of light should be as nearly a point as possible. The oxyhydrogen light practically fulfilled this condition. When this was unattainable he thought that the arrangement suggested by Mr. Traill Taylor at the Conference of the Camera Club was worthy of consideration. This consisted in an adaptation of the alcoh-carbon gaslight fitted to the lantern, two burners being employed, one being about an inch behind the other with an air space between. Interposed between the condenser and the flame, as close to the latter as possible, was a diaphragm having a circular opening half an inch to one inch in diameter, the position of the diaphragm being such as to hide all the light except a portion of the most luminous part of the flame. The ordinary oil lamp had the disadvantage of unevenly illuminating the screen owing to the division of the wicks. He thought, however, that Mr. Taylor's principle might also be applied to oil lamps.

Mr. J. H. BIDD preferred the oxyhydrogen to the oxycalcium light.

The PRESIDENT said that with a little management a good illumination could be obtained by the oxycalcium light. The wick of the spirit lamp should be comparatively long, and should be split into two parts, between which the oxygen should be directed on to the lime. The President then described Professor Fairchild's method of preparing oxygen while the lantern exhibition or demonstration was in progress.

Mr. E. CLIFTON described the Brins Oxygen Company's light, which differed from the ordinary oxyhydrogen light in the use of a small ball of a comparatively indestructible substance in the place of the lime. This light, though admirable for house illumination, had the disadvantage for use in the lantern that the most intense part of the flame was at the bottom.

In a discussion upon lantern slides, the importance of adopting an uniform method of marking was pointed out, and it was explained that the standard system of the Photographic Club, which was now almost universally used, was that a white spot be placed on each of the top corners when the slide was viewed, so that the subject appeared as in nature, or a white line along the top edge.

Mr. CLIFTON spoke of the inconvenience caused by the use of glasses not uniform in size. He advocated that all slides be made on $3\frac{1}{2} \times 3\frac{1}{2}$ plates.

Mr. Higgins showed some slides on gelatino-chloride plates of his own manufacture printed out and toned with gold.

Mr. T. Utton showed a dark slide with bag attachment for changing plates in the field.

Next meeting will take place on Tuesday, September 20. Visitors are invited.

BIRKENHEAD PHOTOGRAPHIC ASSOCIATION.

THE ordinary meeting of the above was held in the Free Public Library on Thursday evening, the 8th instant.—The President, Mr. J. A. Forrest, in the chair.

The minutes of the previous meeting were read and passed.

Messrs. A. H. Martin, E. R. Wear, Joseph Joplin, and Julio Gonzobz, were elected as members.

Prints were exhibited by Messrs. Forrest, Riley, Eaton, Stanfield, and Lange; the latter had some very large ones by Messrs W. Cobb & Sons, Woolwich, taken on Jubilee Day in the vicinity of Westminster Abbey, of the royal procession *en route*, which compared favourably with those taken at the same time by other operators.

Mr. H. H. Williams showed an interesting instantaneous one illustrating the effect of firing a shot into water from an ordinary sporting breechloader; the amount of water raised as depicted was surprisingly great, whilst the spray therefrom had reached a height of some twelve to fifteen feet, and the gun in the hands of the firer, instead of aiming at the point of impact, as would be supposed it should, had "jumped" so considerably as to be represented in an almost horizontal position.

The PRESIDENT read a paper entitled *How to Manipulate the Camera in a Military Manner* [see page 582], the novelty of a camera mounted on a gunstock in lieu of the orthodox tripod exciting a good deal of interest. It was thought by some to be an unnecessary addition to the impedimenta of a photographer, and that similar results could be obtained, when snap shots were required, by simply holding the camera in the hand and pointing it at the object to be taken, the finder showing when it was properly balanced on the plate.

Mr. FORREST, however, thought otherwise, and substantiated his case by showing some excellent prints taken as described in his paper.

A member stated that he dispensed with the use of a finder altogether, as he found in practice that by glancing along the top edges of his camera he could locate a view with the greatest accuracy.

Mr. H. WILKINSON took exception to the President's statement that after thirty yards a lens has no focus, as he had not found it so himself.

Some discussion took place on the subject, with the result that it was thought that the fact could not be looked upon as established, lenses varying much in this respect, especially when of the larger sizes.

The utility of detective cameras was illustrated by an account of a photographer who had recently visited the fleet with one whilst lying in the Mersey, and came away with a large number of views taken on the various vessels.

A number of queries in the question box having been replied to, and the members reminded that the annual lantern slide competition takes place in October, the meeting broke up.

SHEFFIELD PHOTOGRAPHIC SOCIETY.

THE ordinary monthly meeting of this Society was held on the 6th instant,—Mr. A. S. Platts occupied the chair.

This being the last meeting before the annual meeting, Messrs. Charlesworth and Spencer were appointed Auditors, and arrangements were made for a dinner to precede the meeting, which will take place on October 4.

Mr. J. W. CHARLESWORTH read a paper on *Notes on Development*.

Correspondence.

Correspondents should never write on both sides of the paper.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN EXHIBITION, 1887.

To the Editors.

GENTLEMEN,—Kindly permit me to remind intending exhibitors that Wednesday next, September 21, is the last day for receiving *packing cases* from the country, by our agent Mr. Bourlet, 17, Nassau-street, Middlesex Hospital, and also that the same day is the only one for receiving *pictures and apparatus* at the Gallery. Any further information may be obtained from me.—I am, yours, &c.,

5A, Pall Mall East, S.W.

EDWIN COCKING, Assistant Secretary.

PYROGALLIC ACID AND ITS PRESERVATION.

To the Editors.

GENTLEMEN,—Referring to your leading article in last Friday's JOURNAL, I, for one, should be glad if you would give a little further detailed information on methods of using pyro preservatives. I find it utterly impossible to make a solution of pyro and sodic sulphite that is

not highly discoloured, unless I add such a quantity of free acid that the developing action of the solution is so greatly lowered as to render it almost useless for rapid work. Several friends have, to my knowledge, relinquished the use of sulphite on this account. You would, I am sure, do a kindness to others besides myself if you would point out plainly where we err.—I am, yours, &c.,

Icon.

[An article on the subject will be found in another column.—Eds.]

FOREIGN MADE LENSES AND THE MERCHANDISE MARKS ACT.

To the Editors.

GENTLEMEN,—Respecting the Merchandise Marks Act quoted in last week's JOURNAL, it may interest your readers to know that the Act became law when the Royal assent was given to it; and also respecting foreign lenses, Clause 3, Section 2, says, "applies to goods having thereon any figures, words, or marks, or arrangement thereof, as are reasonably calculated to lead persons to believe that the goods are the manufacture of some person other than the person whose manufacture they really are."

Now, gentlemen, you will see by my card, enclosed, that I am much interested in the Act and have studied it in many ways, and I think you will agree with me that according to the above clause that any dealer having lenses for sale not his own manufacture, and bearing his own name on them, and from this time sells them without informing his customer that they are not his own make (in writing and accepted by the customer, see Clause 17), will be liable to a prosecution, and the same rule holds good with any articles of merchandise or manufacture bearing names, words, or marks, &c., and the *onus* is thrown on the defendant to prove his innocence, or that he sold the goods without a guilty knowledge.

I certainly must differ from you when you say "most purchasers of lenses from dealers bearing dealers' names know quite well they are made on the Continent," &c., and consequently are foreign. I should rather say that most purchasers of lenses with a name of any kind on would naturally suppose they were of the vendors' manufacture, or at least manufactured for them. The same would apply to a watch, especially as the English goods bear a better reputation for strength and quality than foreign goods.

There is no doubt that dealers in every trade must now be careful what they are about, as hitherto so many, I will not say frauds, but misrepresentations as to the goods vended have been carried on, especially where names are concerned, that every purchaser must feel glad that some of these practices are now stopped. I could tell you cases that have occurred in the watch trade that would make your hair stand on end, aye, and in connexion with some of our best and most well-known names, and when they have been brought to book have simply returned the money. Now, I am happy to say, all that is at an end, and a prosecution will have to stand instead. Apologising for troubling you with this—I am, yours, &c.,

Clerkenwell, London, September 13, 1887.

I. W.

SUPERIOR WORKMANSHIP.

To the Editors.

GENTLEMEN,—May I venture, as an old subscriber, to ask my brother amateurs through the medium of your columns whether their experience of what is advertised as "superior workmanship," and for which a proportionately high price is charged, runs upon all fours with my own, or whether I am especially unlucky?

I have worked for several years with a $5 \times 7\frac{1}{2}$ camera and changing box by Hare, when, in an evil moment, I thought, for the sake of the extra weight, I would try one of the much advertised light cameras, having in view a long journey abroad. I duly sent £37. 6s. 6d. with the order, which was expressly stipulated for by the maker, a thing, by-the-by, which I will never do again, for I hardly see why I should trust the vendor with my money and risk getting the goods rather than he should trust me with the goods and risk getting his money; any amount of reference, if you please, but no more cash in advance.

[Here the writer enters into details of a commercial nature which it is unnecessary to publish.]

I started on my trip, and luckily encountered so much rough and stormy weather that I could use my camera but little. I say luckily, because, on developing my negatives since my return, I find many of them marked with two scratches across the whole length of the film, caused by the brass screws in the slides projecting on the inside. Of course the negatives are useless. I have written to the maker of the camera, and received in return a somewhat jeering letter about an enthusiastic amateur. So much in this instance for superior workmanship in return for a high price.

Now for experience the second. Having tried my 'prentice hand with fair success at enlarging, I decided to get an apparatus with lantern and condenser to suit my $5 \times 7\frac{1}{2}$ negatives.

I gave the order to a London firm with whom I had previously had satisfactory dealings, although their price was higher than that of some other good makers, but then I was promised superior quality.

The result is that I receive a set of apparatus so arranged that the flame of the lamp cannot be brought within three inches of the centre of the condenser, nor within five inches of the requisite distance from it to give a full disc of light.

In reply to my complaint I am told that they have copied it from that of another well-known house, but if I can suggest any alteration of detail they will carry out my ideas. As I can see plainly that the whole lantern must be remade, I have to send some miles to get a competent man to repack the case with a view to return it. How the matter will end remains to be seen, but this second case of superior workmanship at a high price is rather a caution to amateurs.—I am, yours, &c., H. A. S.

FIFTY SITTINGS FOR A PORTRAIT.

To the Editors.

GENTLEMEN,—In the interesting controversy in your JOURNAL regarding the above subject, there have been many and varied opinions given, but none which seem to refute the original assertion as made in the article on *Colouring as Applied to Photography*. I do not intrude these few lines, however, upon you in order to support Mr. R. Barrett's theory, but upon a matter which touches myself more closely.

The fact is, I wish to take exception to a remark made in your last JOURNAL by your correspondent, Mr. F. Wilcockson, regarding an engraver. He distinctly calls him a *mechanical* artist. May I ask him on what grounds he makes such an assertion? I have always found engravers, who are worthy of the name, to be men of very high artistic training and most superior draughtsmen. I think it rather hard, under these circumstances, that we should be classed as mere "*mechanical* artists."—I am, yours, &c., AN ENGRAVER.

To the Editors.

GENTLEMEN,—I follow with interest the various opinions of your correspondents on the above subject, but regret to say they seem to get away from the original point at issue. If I read aright, I believe Mr. R. Barrett always speaks of *good* work; and therefore it would be best only to argue it from that point, as he was the author of the article which led to the present discussion. Your correspondent, Mr. Wilcockson, gives as an example, in your last JOURNAL, a *coloured photograph*, and that rather poorly done. I think it would be better to consider this matter from the point, not of painting on a *photographic base*, but painting on an ordinary canvas when photography is only looked upon as a *help*.—I am, yours, &c., ONE WHO DOES NOTH.

To the Editors.

GENTLEMEN,—In your JOURNAL of last week "A Painter," in reply to "Free Lance," makes some remarks about the discolouration of portraits. Will you permit me to ask him the circumstances under which portraits in oil (not on photographic base) will become discoloured as described by "Free Lance," and the causes that lead to same? I would also like to know how to *restore* them to their original state. I can well understand the coloured photographs becoming discoloured, as I have had experience of it, but have never had the experience of a painting in oils, by "an artist of repute," too, doing the same thing.—I am, yours, &c., AN AMATEUR.

Answers to Correspondents.

NOTICE.—Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a NOM DE PLUME as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

PHOTOGRAPHS REGISTERED:—

- A. G. Petherick, 11, Alfred-street, Taunton.—Photograph of Jubilee Car of the Taunton Manufacturing Company.
N. M. Phillips, 69, Oxford-street, Southampton.—Three photographs of Rev. Thomas Nicholson.
G. Denney, 21, St. Sidwell-street, Exeter.—Photograph of Theatre Royal, Exeter.
G. V. Yates, Davy's-buildings, Fargate, Sheffield.—Four photographs of Sir Henry Stephenson, Mayor of Sheffield.

- C. TOMLINSON.—We will try the solution.
R. D. H. B.—We have forwarded your application to Mr. Chadwick.
H. A. G.—The prints to which you refer are simply very highly burnished.
R. C.—Crimson lake from cochineal or alizarine lake are not permanent if they are exposed for a long time to sunlight; but the latter is the best of the two.
T. G. B. inquires what is the best artificial light (not electric) for portraiture.—Next to the electric light we should say, all things considered, that magnesium is the best.
C. BUTT.—Guttapercha is not a good material for vessels which are to contain a silver bath unless it be well coated with shellac. Such vessels are in use and are well spoken of at the Ordnance Survey Office, Southampton.
R. C. MACLEOD.—1. The stain looks very much like imperfect fixation and the light acting upon it. A similar stain may, however, be produced by contamination with silver while the prints are washing.—2. The negatives were no doubt not sufficiently washed, and contact with the silver paper has caused the spots and stains.—3. You have over exposed.
C. STEPHENS.—It is very evident that the body of the flame has been very much too large. Cut off the whole except the space of half an inch by placing an opaque diaphragm immediately in front of the flame, and you may depend upon it that sharpness will result unless there is something radically wrong with the condenser. Try this and write again.

COL. GUBBINS.—The exposure given to the print, namely, over two and a half hours, indicates something radically wrong. The light, though apparently strong, must have been of an unusually non-actinic character. Two or three cheap paraffine lamps placed behind the two thicknesses of ground-glass should give sufficient light to enable the enlargement to be made in a moderately short time.

B. H. G. writes: "I have a stereoscopic lens by a noted maker; in every picture I have made with it there is a small circular area in the centre of the plate that is too dark, and which, of course, appears in the print too light. What is the cause of this? and is there any remedy for the evil?"—The evil is what is known as a flare spot. The remedy is to alter the position of the stop by placing it nearer to or farther from the lens. A few experiments will show the exact place where perfectly even illumination will be secured.

W. B. CASSINGHAM writes: "1. I always use distilled water (free from ammonia) for mixing all stock solutions, but when developing I use plain tap water for making up the developer; is this equal to rain water filtered, or would it be better to use the latter for the developer, hypo solutions for plates and prints, also toning bath?—2. Is two ounces hypo to the pint of water sufficient for fixing prints, or is it better to have it the same strength as for plates?—3. How much liquid ammonia ought to be added to the pint of hypo solution?"—1. Ordinary tap water will answer quite as well as distilled for the purposes mentioned.—2. Four ounces to the pint is the best strength.—3. Ten minims.

SPOTTER says: "I use a mixture of Prussian blue, sepia, and crimson lake, with the white of an egg, for spotting prints, and I am annoyed to find that on looking over prints a few weeks old that the two colours, sepia and lake, have entirely faded and left the spots filled up with the blue alone. I use the best colours I can procure from Rowney. If you can tell me the cause of the above and a remedy I shall be greatly obliged."—Crimson lake is one of the most fugitive of colours when exposed for a time to strong daylight, and for this reason should not be used. Madder colours are somewhat more permanent, and are therefore preferable. Madder brown is a very useful colour in spotting photographs.

REX asks: "Can you please tell me how it is that my prints fade so much when I put them into a fixing bath of two and a half ounces of hypo to twenty ounces of water with ten drops of ammonia? I may say that I thoroughly wash prints at first in many changes of water before toning; after toning they are put into fresh water with a pinch of salt in, then in fresh water again before putting into the fixing bath. However dark I have the prints to begin with the result is, when finished, a very weak, thin sort of print."—From the data furnished it is difficult to say the cause of the trouble unless it be that the prints are over toned. We do not see the utility of the "pinch of salt" treatment after toning. If used at all it should be before toning, but this will not account for the trouble.

WORRIED writes as follows: "I am using a ready sensitised paper, and made up two baths as a test, and both after toning (very slowly) a few prints stopped toning, and the prints began turning the colour of the one enclosed (not from want of gold), and the bath was neutral. I let them remain in the bath two or three hours, but they did not attempt to tone. I took every precaution in making the bath, and used three grains of gold, one drachm of acetate of soda, water, twenty-four ounces, as I have usually done for other papers. I should be extremely glad of any suggestion, as I have one quire on hand and cannot afford to waste prints continually. Do you think for a small business sensitising one's own paper is more economical than using ready sensitised paper?"—It would appear that the paper is at fault if it so obstinately refuses to tone. We should recommend our correspondent to try the effect of immersing the prints in a very weak solution of common washing soda—say a piece the size of a hazel nut in a pint and a half of water—prior to toning. The discolouration seems to be due to light while the prints are in the toning bath. On the whole, we think that ready sensitised paper is the more economical when the consumption is small. When the paper is sensitised at home there is considerable waste unless it is used up quickly, and this cannot always be done when the light is bad.

ERRATUM.—In our issue for the 2nd instant, page 553, second column, line thirty from bottom, for "M. Boissonas, of Lyons," read "M. Boissonnas, of Geneva."

A CORRESPONDENT writing from Falmouth, where the Exhibition of the Royal Cornwall Polytechnic Society is now open, says—"The exhibition of photographs is grand."

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The usual monthly technical meeting of this Society will be held on Tuesday next, September 20, at eight p.m., at the Gallery, 5A, Pall Mall East.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, September 21, 1887, will be on *Lenses*. Saturday outing at Rainham. Train from Fenchurch-street at thirty-two minutes past two.

No. 1429. Vol. XXXIV.—SEPTEMBER 23, 1887.

PLATINOTYPE PRINTING.

PLATINOTYPE, though the simplest of all printing processes, is yet liable to be, and is, considerably misunderstood by many who have little practical acquaintance with its methods, this very simplicity, perhaps, being one cause leading to the existence of these false impressions. For example, it is often said there is no control over the depth of printing, merely because it is thought that a print once out of the frame is complete for good or for bad. But it is forgotten that precisely the same state of affairs exists in the case of a silver print; and, as a matter of fact, there is a very appreciable variation in the possible ultimate depth producible in a platinum print, by varying the heat of the developing bath. Thus, if several prints are made from one negative, and it be shown when the first is developed that an error of judgment has been made in the depth, a lower temperature for a too darkly printed, or the bath made nearly boiling for a slightly printed proof, are capable of modifying the depth of colour sufficiently to ensure a batch of good prints, unless the error has been considerable; but at the same time there is not the latitude that carbon printing permits. With regard to the power of judging of the right time to take a print from the negative, those of our readers with any experience of the process will join us in saying that it need be no burden at all. An experienced man will be able to tell, almost as readily as with silver, when a print is deep enough, and if the experience is wanting nothing is simpler than to run a "pilot" print in silver. A small piece of silvered paper is placed under any spare negative, the smaller the handier, and exposed to light at the same time as the required platinotype under its negative, and both are turned down at once. If the latter prove to be correctly exposed the silver print will be a guide for the next exposure, another piece of silver paper being put into its frame and printed along with another platinum; when the silver print is the same depth as the first the printer may be absolutely certain his platinum is right also. Should the trial print be too light or too dark the pilot print may be varied accordingly. In our own practice we generally adopt this plan as against using an actinometer, whether for carbon or platinotype, though we can usually trust our judgment in the latter after simple inspection.

The advocates of silver point out that there is no range of tone in these pictures; but even that is only partially true. Given a particular sample of sensitised platinotype paper, and the variation of colour under control it is true is practically *nil*; but quite apart from the fact that sepia tones are obtainable with the Platinotype Company's materials, there yet exists a decided range in the tones of black that it is possible to obtain with

the process. We suppose the number of photographers who sensitise their own platinotype paper is only small; but, as may be seen in that very interesting monograph on the subject by Pizzighelli and Hubl, the colour of the finished platinotype print is capable of being influenced by variations in the sensitising and developing bath, and also by the sizing material employed. But, be this as it may, with the paper now purchasable ready prepared for use no one need produce a print of that extremely disagreeably cold tone that once was far from uncommon with the process.

There is another property of the ready sensitised papers which is too little noticed: they do not all give the same character of print as regards hardness and softness. We have seen excellent negatives give at one time prints so hard that no one would care to possess them, and on another occasion prints just perfect as regards gradation. The photographer who desires his prints to excel should not ignore, as to our knowledge is commonly done, this elementary piece of platinotype lore. Indeed, we believe that if negatives of unusual hardness are to be printed from, it is possible to obtain from the patentees paper specially prepared to give half tone in excess, which will give capital prints from such negatives. The difference producible by the mere fact of choosing the right paper is sometimes that between what, practically, is success and failure. Now the most ardent advocate of printing on albumenised paper will not claim the possession of this range of qualities by different samples of paper, though it must in justice be stated that in the matter of "hardness" and "softness" of results there is more range among the various papers in the market than many are aware of. In a general way, however, the silver printer varies his results in this respect not by choosing different papers, but by the strength of the light in which he prints, and thus renders some considerable range available for his purposes.

This leads us to the vital point of the process, the question whether in practical everyday work an ordinary unselected batch of negatives may be printed from in platinotype with as much satisfaction as in silver? To get a satisfactory reply to this query we must look at it in two aspects. We must first ask whether for artistic work it is worth while getting prints—in silver, platinum, iron, or any medium whatever—that are only makeshifts, tolerated, below *par*? There can be but one reply. It is that—granting artistic work, and not merely pretty memoranda to be the goal—nothing that is gravely deficient in artistic quality should be produced at all. But then, in actual practice, artistic excellence is not the only goal; large numbers of pictures are produced which are interesting to their owners, and perhaps a few others, whatever their artistic

merit, so that it is evident æsthetic excellence cannot be looked upon as a *sine quâ non*.

The second aspect is as follows :—The peculiar excellence of a platinotype print is its artistic beauty; it has neither the brilliancy, the richness, nor the force of a silver print, but in lieu of them it possesses a beauty all its own, more nearly approximating—though yet a long way from it—the charm of a steel engraving. To print, therefore, an indifferent negative, in what may perhaps be called a special process, would be a mistake, and it is fortunate that it is so. There are negatives in existence which will give albumenised prints of presentable, perhaps, indeed, excellent quality, which it would be useless to attempt in platinotype, as the result would be grey, cold, and flat in the extreme. But given a good negative, well exposed, not too thin, and with a fine gradation and range of tones, and by this process we may obtain pictures rich, delicate, with a complete range of tone from white almost to black, free from heaviness in the shadows, and which, in fact, are, we will not say unrivalled, but most difficult to rival by prints by any process in the whole range of photographic technics.

SULPHITES IN CONJUNCTION WITH PYRO.

II.

But it may happen that a reliable sample of sulphite is not obtainable, in which case a ready means of manufacturing it as required is desirable, and fortunately this is a matter of the greatest ease, the materials and appliances requisite being obtainable in any modern photographic laboratory. These consist of our familiar friend hypo, common washing soda, hydrochloric or sulphuric acid, a glass funnel, some glass tubing, and a bottle fitted with a cork perforated with two holes, or a two-necked Woolff's bottle may be substituted for the funnel and one of the perforations in the cork. If the funnel be employed it should be fixed in a convenient stand and connected with a straight glass tube by means of an inch or two of rubber tubing, the latter so arranged that by means of a pinching clip a liquid poured into the funnel may be arrested, or allowed to flow, as desired. If it is to be frequently used a "separating funnel" with glass tap will be useful. The straight glass tube is passed through one of the perforations in the cork, and must reach to the bottom of the bottle, in the other orifice being fixed a bent leading tube reaching only just through the cork, to allow the gas to escape as formed. If the Woolff's bottle be used, the leading tube will occupy one neck, the other being fitted with a stopper, by means of which the acid is introduced gradually as required.

Introduce a pound of hypo into the bottle with a little water, not necessarily sufficient to dissolve it all, and insert the cork with its arrangement of tubes. In a separate vessel—a deep basin or jar will answer well—place a solution made by dissolving half a pound of ordinary washing soda in a pint of warm water, and into this solution insert the bent tube leading from the hypo bottle, thrusting it to the bottom of the vessel. Have ready a pound of the strongest commercial hydrochloric acid and a stirring rod.

These arrangements made, by means of the funnel and pinch-cock introduce the acid, a little at a time, so as not to set up too violent an action, into the hypo solution. Decomposition with effervescence will ensue, sulphurous acid being evolved and passing over by the bent tube into the solution of carbonate of soda, chloride of sodium being at the same time formed, and

sulphur precipitated in the bottle. Upon the gas passing into the carbonate of soda solution, it displaces the carbonic acid, and a second effervescence is set up as that escapes, and the solution should be constantly stirred in order that the sulphurous acid gas may be brought thoroughly into contact with the undecomposed carbonate. The hypo bottle, also, should be occasionally gently agitated in order to mix its contents. When upon the further addition of acid no effervescence occurs, and the gas ceases to pass over, the operation is complete.

The carbonate of soda will now have been converted into acid sulphite of sodium, or bisulphite, in which condition it may be used for dissolving the pyro, and will prove a powerful preservative, only it will have to be borne in mind that a large allowance of alkali must be made in compounding the developer to neutralise the free acid—one point which a correspondent in last week's JOURNAL appears to have systematically overlooked. Sulphurous acid, it may be remarked, is dibasic—that is, it forms two series of salts, one neutral and the other acid, the latter formed by saturating carbonate of soda, as we have done with the gaseous acid. To make the neutral salt the acid solution is mixed with an equal quantity of carbonate of soda to that used at first; we have next, therefore, to add another half pound of washing soda. In order, however, that the adjustment of acid and alkali may be accurately performed, we will reserve a small quantity—say, an ounce—of each, setting aside that quantity of the solution, and adding to the remainder seven ounces of carbonate. When dissolved, if the solution be alkaline, as may happen if a considerable quantity of the sulphurous acid gas has escaped combination, add little by little from the reserve portion until litmus paper is reddened and bleached. If, on the other hand, it be still acid, add from the reserve of soda, and by using one against the other, the reserve portions will enable the final state of the solution to be left just on the side of acidity.

If the operations have been carefully performed, and the whole or greater part of the gas utilised, the solution of sulphite will now perhaps be over saturated, and will have thrown down a crop of crystals. If so, a little more water may be added to dissolve them. In any case the result will be near enough to a saturated solution to be used as such.

The operation as described may seem tedious, but in reality it is one of the greatest simplicity. At the same time, when a reliable supply of sulphite is available, we are far from recommending its home manufacture; but when it is not readily obtainable, the plan we give supplies an article that may be thoroughly depended upon as a preservative, and which, if carefully neutralised, will be as free from retarding action as can be.

A word regarding the use of the acid-sulphite. Those who attach importance to the purity of the colour of the solution and who desire a preparation of undoubted keeping qualities may, with advantage, dispense with the addition of the second portion of carbonate of soda. But as we have already pointed out, care must be taken that the proper allowance is made in the developer for the free acid it contains. What this allowance should be it is impossible to say without testing the solution, but this is an exceedingly simple matter. If the usual quantity of the bisulphite solution for one developing operation be measured out and diluted with water, and the stock ammonia, soda, or potash solution dropped cautiously into it until, after stirring, red litmus paper has the colour changed to purple, the quantity so added will represent what

has to be used for each plate in addition to that directed in the formula. This quantity may be borne in mind or the formula of the stock solution itself may be altered in accordance with the requirements.

The bisulphite has a further advantage, inasmuch as when necessary it enables a very concentrated preservative solution to be made; for while the acid salt is quite as soluble as the neutral sulphite it possesses about twice its preservative value. In this respect the meta-bisulphite of potash, a more recent introduction, behaves similarly, but we are not aware whether or not it is a sufficiently definite compound.

In many of the modern formulæ in which the carbonate of potash or soda is employed, it is the custom to combine the preservative with both pyro and alkali, a practice adopted for the purpose of ensuring uniformity of action, when the proportions of the two solutions are varied. This appears to us a useless refinement, for slight variations in the proportion of sulphite do not materially alter the character of the image, while, so far as the effect upon exposure is concerned, the increase of the proportion of the pyro solution to meet over exposure will work towards the same end by introducing a larger quantity of acid and so further lowering the energy of the mixed solution.

In conclusion, we repeat that if a pure sample of sulphite be employed, or a freshly made solution such as we have described, and rendered acid before dissolving the pyro, such a preparation will retain its energy and clearness for a very long period, extending, as we have found in our own practice, to years, and if properly used will be free from any retarding influence in development.

ANOTHER Parliamentary session has closed, and the question of copyright in works of fine art and in photographs is left as it was. The projected Bill has, as on many previous occasions, suffered in the "slaughter of the innocents." This, in the present instance, will, of course, surprise no one, seeing the immense amount of time matters of more national importance have absorbed. Perhaps, however, next session, as it has been announced as a Government measure, the long promised, or threatened, Bill—for it is looked upon rather in the latter light by many photographers—may share a different fate.

As the employment of the collotype process is becoming more and more extended, so the necessity of reversed negatives is increasing. Perhaps, of all the many methods by which they may be, and are, produced, that of taking them direct in the camera by the aid of a prism or mirror, is, on the whole, the best; certainly it is the most convenient, and possibly, is the one most generally employed commercially. At the present time prisms are seldom used, except for lenses of small diameter, on account of their costliness. Hence, silvered glass mirrors, placed at an angle of 45° to the axis of the lens, are now almost universally employed in practice. They are cheap, and, if well made, answer the purpose admirably.

WHICH is the best position to place a reversing mirror, in front of, or behind, the lens? In England it is usual to fix it in front, and in Germany—where reversed negatives are more in use than here—at the back. From an optical point of view, it makes very little difference which, but practically the posterior possesses many advantages over the anterior position, and, for this reason, it is surprising that the latter is still retained by so many photographers. When the mirror is arranged in front of the lens, its silvered surface is, of course, exposed to the atmosphere and any noxious vapours it may contain, during the whole of the time the image is being focussed and the negative taken. Hence, it quickly loses its lustre and requires repolishing, which tends to wear away the thin film of silver; it is also liable to accidental abrasion. Again, the mirror has to be removed from the camera every time it is required to change the lens.

Furthermore, when the camera has to be brought close up to the object to be copied, and the lens is of short focus, the fittings of the mirror may obstruct the light, or even cast a shadow upon it. These inconveniences, as well as the disadvantages, may be avoided if the mirror occupies the posterior position. There it is better protected from atmospheric influences and accidents. The lens may be changed without disturbing the mirror or its fittings, and they, of course, will not interfere with the illumination of the object while it is being photographed.

ALTHOUGH the back position for a reversing mirror is far preferable to a front, the best place of all for it is between the components of the combination, which it is scarcely necessary to say must then be mounted at right angles to each other. In this position it is perfectly protected from injury, and is not exposed to atmospheric influences. When so placed, a much smaller mirror will serve—indeed, it need be but little larger than the stop with which the lens is worked. This plan of fitting the reversing media was introduced some ten years or so ago by M. Derogy, but it has not, so far as we are aware, been very generally adopted. It is somewhat difficult to see why this should be the case seeing the advantages it offers.

By the way, reversing mirrors are frequently injured through want of care on the part of those employing them. If they are much exposed to the air during damp and foggy weather, such as that which may shortly be expected, the silver rapidly becomes tarnished, and then a much longer exposure of the negative is necessitated. And it should be borne in mind that every time the reflecting surface is polished the thickness of the thin film of metal is reduced. For this reason the mirrors should never be exposed to the atmosphere for longer than can be avoided, and they should always, when out of use, be kept in a dry place. Before commencing to repolish the surface, care should be taken that it is perfectly dry, for if it be damp the silver may rub off. To guard against this it is a good plan to always make the mirror slightly warm in front of the fire before commencing to polish.

THE present is about the best season of the year for securing good cloud negatives. About the time of the equinox—vernal or autumnal—as a rule, grander cloud effects, and a greater variety of them, are to be seen than at any other period. Few photographers, amateurs in particular, possess a really good stock of cloud negatives, yet they are not difficult to obtain during the early spring and autumn months. Nothing looks much worse in a collection of photographs than to see the same clouds introduced in several different subjects. Yet we often meet with examples of this even in the leading exhibitions. It is to be hoped that in the forthcoming one in Pall Mall such things will not be seen.

IN a recent number of the *Photographische Mittheilungen*, Herr E. Vogel describes different methods of imparting a gloss to platinotype prints, and even for "enamelling" them. Most persons consider that the matt surface and engraving-like appearance is one of the principal charms of platinum pictures. To confer upon them a glossy surface, or, worse still, to enamel them with gelatine and collodion, would be to destroy all their artistic qualities. How would a fine mezzotint engraving look if it were enamelled? Certainly quite as well as a platinotype similarly treated. However, no one with any artistic feeling would think for a moment of doing either the one or the other.

LANTERN SLIDES ON GELATINE PLATES.

II.

IN making an emulsion for lantern slides I vary the process rather materially, both as regards formula and procedure. As the aim is not to make a rapid but a clean emulsion, we can afford to neglect some of the precautions necessary to the production of great sensitiveness, and their omission assists in securing quality and fineness of deposit.

With regard to the formula, I shall give a choice of two which I like equally well, a bromo-iodide and a bromo-chloride, both of which give better tones than bromide alone, and each possessing certain points in its favour. The bromo-iodide gives rich, clear images of various shades of warm brown to black with ordinary pyro development, and the deep colour given to the film by the iodide pre-

vents the spreading of the light in the gelatine itself and helps to give clear, sharp outlines. The bromo-chloride plates give a cooler toned image with ordinary development, but by increasing the exposure and using ferrous oxalate or ferrous citro-oxalate they yield a wide range of warm red colours which will bear toning with gold or platinum.

The proportion of iodide to bromide may with advantage be very considerably increased as compared with what is desirable for rapid landscape plates, and the colour of the image may thus be very greatly modified; but it is not well to go beyond a certain point or a difficulty will be experienced in getting density. In the same manner the proportion of chloride may be increased, but if pyro development is to be employed, this, too, must be done with caution. The two following formulæ represent the qualities I have found best:—

BROMO-IODIDE EMULSION.

Bromide of ammonium	60 grains.
Iodide of ammonium	20 "
Gelatine (Heinrich's or Coignet's).....	180 "
Nitric acid, s.g. 1.4	2 minims.
Nitrate of silver	120 grains.
Distilled water	10 ounces.

BROMO-CHLORIDE EMULSION.

Bromide of ammonium	35 grains.
Chloride of ammonium (or sodium).....	30 "
Gelatine	180 "
Nitric acid	2 minims.
Nitrate of silver	120 grains.
Distilled water	10 ounces.

It may be remarked here that as in the latter formula there is a large excess of soluble chloride, the whole of the soluble bromide being taken up, the difference in the equivalent weights of the chlorides of ammonium and sodium is of no consequence, and either can be used as may be convenient. With respect to the gelatine, I prefer very much to use Coignet's when I can get a sample free from "pits" and spots, as it appears to me to give a brighter and clearer film and to set more firmly than others. Failing that I fall back upon Heinrich's.

Then, again, as we are not in search of rapidity, we are not under the necessity of emulsifying in very weak gelatine in order to bring about the rapid combination of the elements; on the contrary, by preference I emulsify in the full strength of the gelatine, which makes it easier, and produces an extremely fine deposit without the slightest trouble. In order to get what sensitiveness is required, the emulsion will bear a high temperature for a long period without bringing on fog or coarseness or destroying the setting power of the gelatine.

I spoke in my previous article of the desirability, as far as possible, of avoiding the formation of insoluble calcium salts, and the first step in this direction is to use distilled water, and the following is my method of producing a clear, bright solution of gelatine. I may say that I have tried various methods of using albumen for clearing the gelatine, but have not succeeded in finding an efficient one, so have settled down upon the domestic "jelly bag" plan. I dissolve the gelatine, 180 grains, and make up to six ounces with distilled water, after soaking thoroughly also in distilled water, during which time the flakes are thoroughly rubbed one against another to remove as much as possible of the adherent dirt and grease. It is surprising what a quantity of fibre from the nets upon which it is dried becomes adherent to the gelatine, but much of this can be removed in the manner I have described. When the gelatine is dissolved I raise the temperature to about 180° Fahr. in order to increase its fluidity, and then proceed to filter in front of a hot fire. The filter I use consists of a conical bag of swan's-down, double thickness, sewn separately, and the seams at opposite sides. Into this I frequently drop a folded filter paper, but though it then filters less rapidly I cannot say that the action is any more perfect.

This bag I suspend in front of the kitchen fire by any convenient means and as close as may be necessary to keep the gelatine hot; the latter is then left to run through at its leisure, but the operation is by no means a long one, and I usually repeat it. The result is six ounces of a thirty-grain solution of beautifully clear gelatine. I prefer to filter the gelatine in this manner before emulsifying or even bromising, because it can be done without having recourse to the

dark room or elaborate arrangements for keeping up the temperature, and also without upsetting the equivalents of bromide and silver.

Next I add the soluble haloids, dissolved in two ounces of distilled water, and, finally, in the dark room, the silver and nitric acid, also dissolved in two ounces of distilled water and brought to the temperature of the gelatine. No special care is requisite in adding the silver solution very gradually, as is the case when the emulsification is performed in a two or three grain solution. It may be poured in a steady stream into the gelatine if the latter is kept well stirred with a glass rod, or, better, a flat strip of glass or wood. When mixed, the emulsion is left to ripen. This may be done either quickly or slowly, at a high temperature or a low one. No harm is done to the gelatine or its setting powers by boiling for half an hour, but the method I usually adopt is to mix at about 180°, and keep up that temperature or thereabouts for a couple of hours, when I find the sensitiveness all that I require, namely, about ten on the Warnerke sensitometer.

The next operation is the freeing of the emulsion from soluble salts; to effect this it is first allowed to set thoroughly. There is no necessity for the use of ice for the purpose of causing it to set hard, except, perhaps, in abnormally hot weather; if the jar or vessel be placed in cold water, or a wet cloth be wrapped round it and water allowed to trickle slowly on to it, the contents will be found quite firm enough at the end of a couple of hours, but the best plan is to leave it all night.

The mass is next pressed through coarse canvas, or otherwise divided into small fragments, and covered with distilled water, in which it is allowed to soak for ten minutes; this is poured off and replaced by a fresh supply, the divided emulsion being well stirred and again allowed to soak for ten minutes or a quarter of an hour. After this three or four more changes of distilled water are used, but each is allowed to remain for an hour and the emulsion stirred at intervals.

Another plan I sometimes adopt if I have not sufficient distilled water at hand is to precipitate with alcohol. The ten ounces of emulsion is allowed to cool down to about 120°, and then a pint and a half of methylated alcohol carefully filtered and raised to the same temperature is poured into it and briskly stirred; if on the addition of the whole of the alcohol the emulsion does not separate continue stirring until it commences to clot, and as it cools down it will be found to separate in a far more convenient form than when the alcohol is used cold. In that case the emulsion solidifies into a tough, leathery mass, which is difficult to treat in any manner, but by warming the alcohol the precipitation is more gradual and in the form of separate clots.

Drain off the mixed alcohol and water, which now contain the whole of the soluble salts, or nearly so, and cover the emulsion with distilled water, leaving it to soak for an hour to extract as much as possible of the alcohol left clinging to the spongy mass of gelatine; repeat the treatment once more, then remelt the emulsion and make it up to ten ounces. Or, if preferred, after precipitation the emulsion may be dried and preserved in that state for future use. This will be found very convenient when only small quantities of emulsion are required at distant intervals, as the one trouble of manufacture will serve for several batches. If thoroughly dried, as it should be to keep well, thirty grains of the "pellicle" will be equivalent to one ounce of emulsion, and simply requires soaking for an hour or two in distilled water previous to dissolving by heat.

Beautifully clean results may also be obtained by means of any of the "precipitation" methods of emulsification, that is, when the silver haloid is formed in so attenuated a solution of gelatine that it may be separated by subsidence, or, as in Monckhoven's plan, when washed carbonate of silver is converted into bromide by means of hydrobromic acid. These, however, involve a considerable amount of trouble and, in the latter case, chemical calculation, and are in no way superior to the simpler method I have described.

However the emulsion may be completed it must be finally filtered before use, but if the first filtration of the gelatine has been properly done, simply running the emulsion itself through a double thickness of muslin is all that will be required.

The plates should be very thoroughly cleaned and polished before coating. I prefer, though it is more trouble, to polish the glass

finally with powdered talc, but this necessitates a subsequent very careful dusting to remove any adhering particles, which would cause spots if allowed to remain. Still the treatment appears to give the gelatine a better hold of the glass, besides rendering the plates less liable to slight veil in the shadows, apparently between the film and the glass.

It will well repay the trouble to exercise very special care in coating and drying the plates. I prefer to coat and level each little plate separately, and to examine carefully for defects before placing in the drying cupboard. It may consume more time, but in an hour or two a very large number of plates can be coated, and the satisfaction remains of knowing they are as near perfect as can be attained.

Methods of development must be reserved for a concluding article.

W. B. BOLTON.

COLOURING AS APPLIED TO PHOTOGRAPHY.*

HAVING carefully and successfully accomplished our *washes*, and got them evenly over our photograph, we can (having *picked or wiped* out our high lights) proceed to perfect our work by the aid of *hatching* or *stippling*. We have the option of style, as both these systems of work will yield the most satisfactory results, or a judicious treatment somewhat between both will enable you to produce a good picture. Stippling alone will give a very fine and elegant finish to a portrait, but it will necessarily lack breadth, and sometimes vigour, and this would in some cases be very fatal to the production of a faithful likeness. I am sure, on thinking over it, you can call to mind many faces that could not be done justice to by such a system of work as stippling, and this only on account of its fineness of texture and natural beauty, but which would neither lend themselves to the semblance of the original.

In the same way, by *hatching*, a very beautiful but bolder style of portraiture can be successfully produced, but there are many subjects much too delicate in themselves to be faithfully represented by such a treatment. Of course, a good likeness may be secured, but there will be something wanting. This want will be found to be simply texture—in other words, the treatment is not delicate enough to adequately represent the appearance of the original.

Both these styles are good in themselves, but they have each their favourable class of subject, and therefore I advise a mastery over both, in order that, by a judicious intermingling of both, the student may be able to gain any result that may be required. Not only this alone, but he will be able to impart vigour, feeling, and breadth to even the most delicate subject he may be called upon to paint, and of course in his bolder subjects can produce any degree of fineness or finish that may be desired, and yet preserve the natural and distinctive features of the original. I have seen most beautiful results in both these styles in their purity, and, from an artistic point of view, could naturally not help admiring them; but, as I said before, they each require their special and favourable subjects to be *truly successful* as portraits. Of course, I am laying down my principles from the standpoint "that the nearer we get to nature the more perfect is our work." I have positive ideas on some subjects, and this is one of them—a portrait *must* be a *likeness*. If a likeness be not secured, I will not have it as a portrait, no matter what its artistic merit may be as a *picture*. I think, too, that all students should *start* with the same principles, however much they may afterwards wander away from them.

We will now direct our attention to the methods of working these two styles. We will take *hatching* first. HATCHING may be said to consist of working your colour in a series of short strokes, which may almost be termed lines, but observing carefully that they follow as nearly as possible the form of the various features. Considerable study and practice will be found necessary to acquire a perfect knowledge of the directions in which these lines should go. The least mistake in such a case would not only spoil the result you have in view, but would be absolutely fatal to it. The more closely the student examines this the more he will recognise the fact. If it should not appear of sufficient importance to him, let him (after having acquired a mastery over the correct style) alter or falsify the

correct direction of these lines, and I feel sure I can leave the results to speak for themselves.

It will be found that these strokes or lines should take a somewhat horizontal direction on the forehead; they will be somewhat curved about the eyes, mouth, and general contour of the face and neck. This completed, these strokes are then crossed with others of a similar nature. These, however, must never cross the first lot at anything approaching a right angle, but rather, although *crossing*, preserve a feeling of appreciation as before for the formation of the feature under treatment. All these strokes should be produced by a firm touch, although at the same time the brush should be rather lightly held between the fingers, and with an effort to keep each stroke as equidistant from the other as possible.

Another point to be cared for is the working and condition of the brush while hatching. The colour should be carefully mixed, and be neither too dry nor yet too moist. The necessary moisture of the colour is considerably influenced by the material one is working upon. If this be not attended to, or the brush charged with too much colour, it will be found that a kind of blot or blob, as it were, will be deposited at the end of each stroke. This, it is needless to say, would be ruinous. In larger styles of work, hatching is almost exclusively practised (stippling being practically useless beyond a certain limited dimension), and should therefore receive a due amount of attention. In water colour, speaking generally, it may be considered the chief method of working the flesh, and should consequently be practised in every possible way in order to acquire a thorough certainty and freedom of hand, which alone can secure artistic merit for your work as well as make it a success as a portrait.

Stippling will be found to be a somewhat similar process, except that fine dots made with the point of the brush are employed instead of the strokes or lines of hatching. As in hatching, regard should be given to the formations of the features, although in stippling one is not so bound by them. A face will not be very artistic or satisfactory even with a system of fine dots evenly worked over its surface, no matter how regular and carefully placed they may be. No; due consideration must be given to the various formation, and the greatest care taken to preserve same while working.

Whether hatching or stippling, the result we want to secure is depth, and at the same time transparency. Besides this, by such treatment we secure or retain a much greater purity of tint than could ever be accomplished by a washing of mixed colours. There are many delicate touches of colour that can be placed just where required which would be impossible except by the aid of these methods. This, perhaps, will prove sufficient to say on these points.

I will now give a few *hints* which may be found worth keeping in mind when working, and which apply alike to all classes of painting, whether in oils, water, or dry colours.

It will be observed that all *fleshes*, as they retire from the eye, appear to become colder in tone, and must be treated by us accordingly, or we will fail to reproduce a truthful result.

If closely observed, it will be found that all the *high lights* of flesh incline to somewhat of a *yellowish* white. Often, by inattention to this fact, many careless painters lose considerable effect, or at least mar it.

The judicious balancing and keeping in proper subordination of what may be termed the *half lights* in comparison to those of greatest prominence will impart brilliancy, and do much to enhance the general effect and vigour of your picture.

As *shadow* may be described as the *absence of colour* (for without *light* there is no colour), so every gradation, as it deepens in its progress from light to shadow, must be adequately represented by a gradation from colour. The colour, therefore, in all shadows should never be vivid or bright, but be always kept in thorough subordination. Sometimes, one is obliged by surrounding circumstances to make the colour visible, but in such cases it should be depicted in the most subdued tone.

On close examination, it will be found that *local colours* are not visible in the highest lights, as also in the deepest shadows; but, if considered well, this fact will be found to be the inevitable result of nature as it affects colour. The edges of all *reflected* or *cast* shadows will be observed to be of a *grey* tone.

All *warm colours*, or those approximating in hue—be they simple

* Continued from page 570.

or compound—to either red or orange, *advance*, and become assertive in a picture.

Cold colours, or those approximating in tone to blue, will, on the contrary, *retire*, and give the idea of going into distance.

By *contrasts* brilliancy of effect may be gained, but the greatest care should be taken not to make same too violent, and certainly not inharmonious.

As for *style* of execution, I consider it should be to a great extent governed by the subject under treatment, as it should aid considerably in expressing character. Thus, in a man, in should be bold and vigorous, while in a woman delicate and tender.

In laying colours, one should rub as little as possible with the brush, and thus aid in keeping them bright and fresh.

In all work avoid harshness; no line should be left unsoftened. It will be found that in nature there are no real outlines, although the boundary of sight seems to be distinctly marked.

All cast shadows should be painted of one tone and of as *warm* a hue as possible, except at the edges, where, as I said before, they must be greyish. The local tint, whatever it may be, must naturally influence the carrying out of this arrangement.

Reflective lights, too, should be kept warm, except in cases where the object from which they are thrown is visible, in which case they must partake of its especial colour.

In cases where the outline of a figure may be *ungraceful*, and for some reason it may not be advisable to alter the drawing of it, it should be judiciously lost, as it were, in the shadow of background to such an extent as may render it no longer offensive to the eye.

The massing together of lights and shadows will result in breadth and grandeur of effect. In this the background will aid considerably when managed by skilful hands.

All shadows should be kept as transparent as possible, never heavy and opaque.

The purer and more transparent colours are kept the better. They should be most truthful to the subject, and be in general harmony, not only with each other, but with the general tone and nature of the picture.

One of the most essential qualities of a background is that it should *retire* from the figure, and should not seem to *rest upon its shoulders*, and the figure, in turn, must not seem to be as it were cut out and laid on. In other words, we must try to produce atmosphere.

We should be unceasing in our efforts to preserve *breadth* of light and shade in our pictures. This quality is absolutely essential to success, as, without it, no matter how careful our manipulation may be or how elaborate the general finish, our picture will be without any real merit.

As regards the *likeness*, constant reference to the duplicate photograph when the sitter is not at our disposal will be sufficient help in this respect. A picture in which all these qualities are carefully and consistently carried out will possess no little value as a work of *merit*, if not quite a work of art.

REDMOND BARRETT.

ON A NEW PRINCIPLE FOR THE CONSTRUCTION OF PHYSICAL INSTRUMENTS OF QUANTITATIVE MEASUREMENT.

II.

For six months, after inventing the chain and other arrangements described in my last article, and by means of which I have been enabled to convert the Cartesian diver into an instrument for the measurement of pressures at constant temperatures, I felt quite convinced that its compensation for temperature was impossible. As the temperature of a gas increases, so does its tension, and that directly if our temperatures are counted from the rational zero of $-273^{\circ}\text{C}.$, and to compensate the Cartesian pressure indicator for variations in temperature requires that for each degree of temperature to which it is subjected a corresponding fraction of pressure to the air contained within the diver must somehow be applied. During the six months in which I had this problem of a possible compensator engrossing my attention, I had the jar with the balloon and chain in use as a barometer. The jar was open and carefully kept filled to a certain

point, and a thermometer was affixed inside. By means of tables, showing the tension of airs and vapours at different temperatures, I was able to deduce the barometric variations of the outer air, and found the instrument to work extremely well and to be altogether

more sensitive than either the mercurial or the aneroid barometers. Daylight, however, dawned on me at last. The containing vessel must be in reality a thermometer, and force up a liquid column in such a way as to produce the increase of pressure needed with increasing temperatures, and I produced an arrangement of the kind depicted here. A tube suitably proportioned to the capacity of the jar was secured in firmly by an indiarubber "cork," the whole thing being completely filled with water at the highest temperature to which it would have to be exposed, and a drop or two of sperm oil floated on the surface to prevent evaporation. In this arrangement, as the temperature of the liquid in the jar diminished, so did the temperature of the air and vapour in the balloon and their tension with them, and in an arrangement properly proportioned the liquid column descended, and so far diminished the superincumbent pressure as to leave the balloon in the same position of elevation as it was in before the reduction of the temperature. In fact it was sensible to the barometric variations only, and uninfluenced by the temperature of the jar. The form and proportions of the thing were not to be desired. Whatever the capacity of the jar might be, the tube would require to have one definite length above it to compensate for a definite range of temperature.

To give a concrete example. Suppose water to be the liquid used, and the range of temperature to be from 50° to 90°Fahr. , the tension of the mixture of air and aqueous vapour would equal a column of mercury 3.448 inches high, and would necessitate an aqueous column for its regulation of that number $\times 13.59$, the specific gravity of mercury $\times 1.0045 \div 1.0003$ for the diminished specific gravity of the waters between the temperatures named, or, say, 48.9 inches in all, which on the top of a jar one foot high (having a reading space of nine clear inches for three nominal inches of the mercurial scale) would leave us with an instrument over five feet high. To obviate this height I resorted next to the use of a mercurial compensator as depicted

Fig. 1.

Fig. 2.

in Fig. 2, and the original instrument is in my possession now. In this arrangement, as the mercury descends in one limb whilst it rises in the other, the actual linear movement in the tube required to produce a vertical pressure of 3.448 inches is but half that quantity, or 1.724 inches.

Accordingly, with a mercurial compensator, the Cartesian barometer may be so reduced in size that the reading space may occupy three-fourths of the length of the whole instrument, and this in the instance of one a yard in height—about the length of most mercurial barometers—would afford spaces of nine inches each as representative of the nominal inch of the mercurial scale.

In my next I propose to give another variation of the Winstanley Cartesian manometer, in which philosophical value is coupled with something of artistic form, and that in such a way as to make the apparatus readily available

for conversion into, or for the foundation of, a perfect crowd of physical instruments of quantitative measurement.

I predict for the Winstanley Cartesian principle a place of usefulness which will never die, but to which the now living partner in its production will be indebted for the bitterest of all possible combinations of bitterness—for a premature death, and for something hideously suggestive of a martyr's grave.

D. WINSTANLEY.

THE IRIS DIAPHRAGM.

In a recent reply to a correspondent it is said that "the iris diaphragm is about as good as any other." As I have this summer been using some lenses fitted with this diaphragm, I hope you will allow me to say that I think it has points which may well cause it to be preferred to "any other."

In the first place, there is no fear of either losing the diaphragms, mislaying them, or leaving them at home. All these misfortunes have happened to me with Waterhouse diaphragms. I remember once spending a couple of hours on Little Orme's Head in a fruitless search for a favourite diaphragm ($\frac{f}{8}$) which had dropped out of its slit as I was carrying the camera on my shoulder; intending to employ this stop only I had brought no others.

Then with the "iris" there is no slit in the lens tube to weaken it, and—worst of all—to admit light. The nuisance of fixing indiarubber bands, tying on handkerchiefs, &c., to exclude this light, must have been experienced by every one who uses the ordinary "stops."

In focussing, it is a great convenience to change, in a moment, from full aperture to any opening required, or *vice versa*, by the simple revolving of the "iris" ring. There is no bother of changing or fitting in stops.

Another advantage is that almost any aperture may be obtained, intermediate between those marked upon the mount, by previously measuring the size of the opening. This is often useful when it is desired to compare lenses, &c., which, perhaps, have not similar stops.

Lastly, the "iris" is lighter, more compact and self-contained, and is free from risk of bending or breaking.

The "iris" diaphragm was introduced, for microscopic work, by Messrs. Beck, I believe fully thirty years ago. But it may be said to have been employed in photography also during that period, for the objectives so fitted were used for photo-micrographic purposes by some of our best workers.

Attempts were also made at intervals to introduce the "iris" diaphragm into ordinary photographic lenses. Thus, in a volume of *THE BRITISH JOURNAL OF PHOTOGRAPHY*,* which I happened to be looking over this morning, I see that at a meeting of the North London Photographic Association, Mr. How, of Foster-lane, exhibited a lens-mounting which is thus described:—

"In the place where the diaphragms (*à la* Waterhouse) are usually inserted was a lever, on moving which to one side the diaphragm in the tube was made to contract. When the lever was at one side the diaphragm was at its largest, when at the other side it was contracted. This was effected by the diaphragm consisting of a number of pieces (each one hinged on a separate pin) placed on a disc, all inside the tube. By means of a volute curve, or some similar contrivance, the motion of the lever caused the free ends of these pieces to move in the direction of the centre of the tube, and, as all moved simultaneously, the aperture in the diaphragm plate was correspondingly diminished. Although in the particular lens exhibited there was no index by which the exact aperture could be ascertained, yet Mr. How explained that in the other lenses which were in his possession that had been provided for.

"The Chairman (Mr. W. Hislop) said that, looking at the lens in a mechanical point of view, it was a very efficient form of diaphragm, occupying a small space. In using the ordinary diaphragms it was not pleasant to drop one through a chink of a rock and have to extemporise a cardboard substitute. The present arrangement would obviate that, and it seemed to be as perfect an one as they had ever had brought before them."

For some years past Messrs. Beck have extended to their photographic lenses the "iris" system, which they originally applied to microscopic objectives; and I feel sure that those who have once experienced the "comfort" of this plan will desire that all other opticians should follow their example. W. JENOME HARRISON.

A DEFENCE OF THE AREA SYSTEM.

SCIENCE simply means knowledge, but is generally used in the sense of perfect knowledge, or rather what is accepted as such. It is not, however, a fact that we have a perfect knowledge of any branch of "science." Many of the laws deduced by scientists from the facts known, imagined, or even invented, are, and probably ever will be, subject to change as we progress towards more perfect knowledge. The highest professors of many branches, probably of all, differ from one another as to the laws as well as the facts. Science, for instance, has done wonders for the manufacture of iron and steel, particularly the latter; but something must be wrong in the application of it when the unlettered men of the Soudan had infinitely better weapons, as far

* See number for February 24, 1865, page 103.

as regards quality of the steel, than our troops. As a matter of fact, everybody cannot be right when many disagree, and, as a matter of opinion, there are not many laws yet established that may not some day be proved false.

There is only one book in the whole literature of the world in which no one yet has found a flaw—*Euclid*, which is a pure type of reasoning, not logic, which I take to be a system of hair-splitting as generally practised. Every premiss is first carefully stated, and, if agreed to, all the rest is so clearly stated, step by step, that flaw finding is impossible. In ordinary science it is quite otherwise—a *dictum* of one man is often accepted as fact. If it prove fallacious, what becomes of the theories and laws based upon it? The moral is never to take anything in print for granted, but, if the subject matter interests you, try for yourself and see if it agrees with your own experience.

If there is one thing upon which everyday practice agrees with science teachings, it is in certain properties of lenses. It is to these that I now wish to call attention. The properties that are not disputed I believe to be these—that if a given stop with a given lens requires an exposure of one second, then a stop of half the diameter would necessitate four times the exposure, and one of one-third the diameter nine times the exposure. That if a given stop with a given lens requires an exposure of one second, then if a lens of double the focus were employed with that stop four times the exposure would be necessary, and if one of three times the focus a ninefold exposure is required—approximately.

If this is admitted, it necessarily follows that a system based on their areas in some form or other is desirable, if only as a ready way of ascertaining the relative exposures that would be optically equivalent with the many varieties of lenses and diaphragms in general use, as affording a more ready and easy way of comparing results obtained.

First of all, the focus of the lens must be found, as, according to the modern system, the sizes of the stops depend upon this being known more or less accurately. In those happy, early days, before science came to the attack (or shall I call it rescue?), a good deal of good work was done with very simple appliances: a single lens, often not even achromatised, was most generally used, and, as a matter of fact, it was measured and described by its *back focus*—that is, by the distance it was from the convex side of the lens to the plate. And a very good arrangement it was, for, by good luck, it happened to be nearly scientifically correct as well as practical. This got to be such a habit with the majority of us poor common folk, that the scientific opticians who catered for us were obliged to give the *back focus* as well as the equivalent focus of their doublets before we could understand how to make use of them. We persevered, however, and tried to learn the proper meaning of equivalent focus, and to get at the reason why a lens was called a six or a ten-inch equivalent focus. Slowly and painfully it dawned upon us that although we could not measure it and make it agree with its supposed focal length, it was probably quite right. We also had a hard struggle to find out the value of the stops employed in these doublets, which were mysteriously placed, sometimes in front, sometimes between, and sometimes behind. Then our difficulties were in no way lessened by the announcement, by the great high priest of photographic lenses, that the value of the stop when placed between the lenses was materially affected by the increase of effective aperture occasioned by the convergence of the light rays by their passage through the front lens of the combination. We passed through a further vale of agony when it was discovered that the increased number of reflecting surfaces had also to be taken into consideration and allowed for. Practically, I do not think we any of us hothoused ourselves any more about the matter. A large number pinned their faith to the high priest and gave him all the credit he deserved, other priests arose and following them or the glorious old-fashioned rule of thumb, the remainder jogged along their own way; all, or, at any rate, most, doing excellent work, but without being able to communicate scientifically how they did it, thus fully corroborating the old adage that "an ounce of practice is worth a pound of theory."

Still there was a widespread feeling that some definite system should be established, and a Committee was appointed by the Photographic Society of Great Britain to settle the whole question. It was duly considered and decided that, as the exposure depended upon the proportion which the diameter of the stop bore to the focus of the lens, the unit of stop should be made one-fourth the focus of any lens, on the supposition that that was the largest aperture available. This was evidently an error of judgment, for the most rapid lens at that time worked with a very much larger aperture, the focus of Dallmeyer's 2c lens being of six inches focus, working with a full aperture of two and three-quarter inches, as much larger than the unit settled by the Photographic Society as 1000 is greater than 375.

That this was an unfortunate beginning of a settlement is self-evident, from the fact that Dallmeyer did not adopt it. As a matter of fact, out of sixty lenses which he catalogues, and which are supplied as the very best that can be made, each necessarily being fitted with the most suitable stops, there is only one in which the stops are calculated on the basis proposed and decided upon by the Photographic Society. He not only did not adopt it, but his son and successor has not adopted it either, but has continued on the old lines, with another plan of his own, not one whit less scientific or, I may add, impracticable. Curiously enough, though in most cases exact inches, occasionally quarter and half inches, are quoted for the focus of the lenses, the diameters of the stops are measured to the thousandth of an inch, possibly because the exact equivalent focus of the lens is not of such vital importance after all. If it be, think of the labour involved in correcting the stops to the tabulated accuracy. They already require six places of decimals, that is, seven figures, to show their rapidity by the Photographic Society's standard.

Although not a member of that Society, I ventured to point out that the practical plan would be to establish a definite unit by which all stops could be measured and made. That then the stops bearing definite numbers would have their relative exposure values with any lens, as soon as that lens's focus was ascertained. I was not at that time prepared to do more than suggest the unit, but I am more than ever convinced that the unit which I have adopted for my area system is the only one practicable or possible. It is the unit of one-sixty-fourth of an inch.

The reason that this is the only one possible is that all mechanical drills are made to that size, and that size only. The number of the drill is always, as exactly as may be, the diameter of the hole it drills in sixty-fourths of an inch.

If it be objected that the metric system is or may be also employed, I reply that that makes no appreciable difference whatever, for if the measure be taken in tenths of millimetres, four such units are so near to one sixty-fourth of an inch that the error is only 19 in 2500, an amount of error that would be practically inappreciable as well as inevitable by any system of measurement.

My system applies, first of all, and most important of all, to the stops. It is highly important that every one shall be able at once to verify the size of his stops easily and with fair accuracy, while it would be equally desirable for him to be able to verify the exact focus of his lens; but, as will be seen, that is a very different matter when it comes to the test of practice. Theoretically and scientifically it is all *abc*.

Technical education is the cry of the day; but here, again, the theorists are at loggerheads, with but scant hope of a speedy solution of the problem of how to apply it so that it may be of practical use. For myself I admit the value of both, provided that theory agrees with practice. When it does not—as, for instance, the geniuses who lecture on modern chromatrics delight to boast—so much the worse for theory. A little knowledge is a dangerous thing; certainly theories are dangerous unless supported by practice.

Science is a grand-sounding name, and employs big-sounding names to express itself, but it has still much more to do before it will be exact or beyond suspicion of error. The greatest professor best knows his own ignorance. Still, I hope we all work on trying to know, and are therefore science students.

A perfect lens is still a *desideratum* at which hundreds of willing hands and brains are working, and many hope that photography will benefit by the improvements that will be made. In some respects these hopes may be realised, but there is very little probability of their in any way revolutionising the ordinary practice of photography, for it will never give them lenses that will take landscapes with a large aperture, or in any material way alter the conditions under which we work now. With the most perfect lens imaginable there would be, to all intents and purposes, precisely the same necessity for stopping down when occasion requires, and therefore all the more necessity for some clearly understood and easily practicable method of measuring and marking photographic lenses and diaphragms. I, therefore, particularly conjure even those who are content to let things stay as they are, who are quite satisfied that their lenses do all they want more or less to their satisfaction, to give a thought to the future, and try if we cannot decide upon a system on which they had better be marked.

Now the question of getting the focus of the lens is just the one which is so very simple from a scientific point of view but so very difficult from the practical point of view.

The principal focus is always assumed when a scientific article is treating of a lens, but practically—even by opticians—it is so rarely that I feel I may almost say it is never actually used. If it is ascertained, it is invariably most roughly stated in quoting telescopes,

microscopes, and photographic lenses. There must be some reason for this to outweigh the craze of the times for science, and it is simply that, except in the case of telescopes, lenses never work at their actual principal focus, and that even in these it has not, so far, been found necessary to specify it.

For photographic purposes, ordinary telescopes, opera-glasses, and many other purposes for which lenses are used, if I am credibly informed, the manufacturer's plan is simply to try them, and, if measured at all, it is simply a moderately distant object that is chosen, and the focus is taken as the distance from the cell in which the lens is placed for examination to the focussing screen. He can, of course, if he likes, and if occasion demand it, establish it more accurately, but, as a matter of fact, as he has also to make the mount to suit his lens, it is this practical measurement, rather than the scientific optical centre, that he requires. But, at the best, it is a somewhat elaborate calculation or experiment, and one quite unsuited to the *go* of modern times.

I was taken to task at the meeting of the North London Photographic Society for the reason that, in my paper on the area system I gave it as a practical solution to the problem what exposure to give to two combined lenses of which the several exposure value was known, as, add together and divide by eight, on the plea that this was not scientific, and liable to error amounting to 100 per cent. I grant that from the point of view of the pseudo-science teacher who trusts to theory rather than practice (and neglects the *abc* even of his science, as was done in this case), my plan was anything but scientifically accurate.

I was perfectly well aware of Mr. Traill Taylor's excellent formula, though I do not pledge myself that it is scientifically correct. It looks right, and has the splendid merit of being apparently delightfully simple. You have only to know *a* and *b*, which are the foci of the two separate component lenses intended to join together, find *c*, which is the distance they are apart in the mount, and then *d*, the combined focus, comes out of itself almost like magic. The real difficulty—fully appreciated only by experts—is just this finding *c*, which is the sum of the two possible errors of *a* and *b*, while if *c* is neglected altogether, as was blandly admitted, it vitiates the scientific theory absolutely and completely. As a matter of fact, this pseudo-scientific craze may be carried too far. It has not hitherto been found either necessary or practicable, while the practical means of approximate measurement are well known to those who want to know. As a further matter of fact, I made many scores of practical tests of various combinations, and worked them out by all kinds of formulæ which never really agreed, while I found that my rough-and-ready plan was eminently suitable for everyday use, and practically did not in any case exceed an error of ten per cent. Happy the man who can judge his exposure to that degree of certainty. However, this is no fault of the area system—which is quite capable of yielding the highest possible degree of accuracy that may be considered necessary or desirable—but my fault, if fault it be, for not giving a scientific conundrum to be worked out instead of a practical rule which I have tested and proved as fairly accurate.

I, therefore, once more bring the area system before the photographic public, believing that it will be for their own interests—I have none whatever in it myself except that of a fond parent.

GEORGE SMITH.

ON THE FADING OF SILVER PHOTOGRAPHS.

II.

It has been alleged that ozone exercises an active influence on the fading of silver prints. It appears to me that this idea must have been hastily deduced from the fact that such pictures are more liable to fade during the prevalence of thunderstorms and continued wet weather, or when they are exposed in places near the sea. These certainly are the conditions under which ozone is most abundantly found in the atmosphere; but it remains to be proved that this gas is the predisposing cause. I have, however, made an attempt to solve the question.

Ozone has been very aptly defined as three volumes of oxygen condensed into two. It is naturally formed in various ways during slow oxidations, for instance, those of ether, turpentine, benzene, &c., by violent action on water where it is beaten into spray; by electricity discharged through atmospheric air or dry oxygen. Indeed, during a thunderstorm and by the seaside, when the waves are breaking on the beach, it often manifests its presence by its peculiar smell. From its tendency to part with a volume of its oxygen it is a powerful oxidising agent, and possesses considerable bleaching properties. It oxidises silver, but not gold or platinum. Hence, two of the prints which I subjected to its action were untuned, so that I might the

more correctly note the change, if any, that occurred. The following plan of testing was adopted.

The halves of two freshly prepared silver prints (untuned), one on plain and the other on albumenised paper (No. 1), also the halves of two similar prints (gold toned), badly faded (No. 2), were enclosed in a box and subjected for eleven days to the continued action of ozone, generated by means of the slow oxidation of phosphorus. These prints were examined daily and a fresh dose of ozone liberated on them for about two hours. At the end of that time the freshly prepared prints had not suffered the least damage, while, to my surprise, the yellowish and partially faded ones were greatly improved in appearance. Not that the image itself appeared to be altered, but the yellowness had almost entirely disappeared. The texture of the paper, however, seemed to have suffered considerably, and the prints required careful handling. Presumably, the ozone had oxidised the sulphurous compound into a sulphate.

This solitary experiment must not be considered by any means conclusive, but, on mentioning the results of it to a picture restorer, he observed, "Why, that's nothing new, for it's the plan we use for restoring old etchings and engravings, and has been in use for years by those who are in the secret."

It may possibly be that some day we may find out that this same ozone may turn out to be the photographer's friend instead of his foe, if we could only find out the best means of utilising its peculiar properties.

GEORGE DAWSON, M.A., PH.D.

P.S.—Having, Quixotic-like, attempted to demolish this ozonic windmill in mistake for a giant, I shall endeavour, in my next communication, to point out real dangers and the best means of avoiding them or, at least, mitigating the effects of those that must necessarily be encountered, and which affect the stability of silver prints.

THE PHOTOGRAPHIC SOCIETY OF INDIA.

WHEN an amateur photographer has mastered his art in all its technicalities, it becomes a question of "What will he do with it?" His taking up photography, *ipso facto*, presumes that he has taste, but taste alone will not supply those principles of picture making an artist has to acquire by study. The cultivation of the art faculty is of primary importance, it gives the hall mark to his production. The closely following of the art literature of the day, and a current interest in art matters, will always prove an incentive to a higher order of work in photography. Hamerton's *Portfolio*, for instance, goes a long way to expound the ethics of art. The study of etching will prove of particular value to the photographer, who should emulate the velvety masses of shadows in all good examples.

Etchers are careful in the printing of their plates, whose artistic qualities are personal equation with the artistic ability of the printer. Photographic printers consider a negative good if it prints rapidly and with little or no attention.

There are instances of coppers being sold at a fraction of their value, because they were supposed to have been worn out. In the hands of artistic printers, their printing value was proved to be considerably greater than even originally imagined by the artist. Hayden's etching of the *Breaking up of the Agamemnon* was almost discarded by himself. Altogether it fetched him a sum of 2500 guineas, or three guineas a minute for the time spent on his work.

The Ialmagundi Club of New York, to take one of many examples, may read us a valuable lesson as photographers. A subject is announced by the presiding member, and each artist is supposed to embody it in artistic form. The results, on a particular evening, are produced for mutual, but not necessarily complimentary, criticism. On the particular occasion referred to, the subject was Silence, and in the *Scribner* of January, 1880, will be found illustrations of works produced in paper and canvas and in clay; these essays are worth studying for the impetus they give to artistic feeling.

Photography may make similar essays. The artist has for his model the human figure—the purpose he supplies—his photographic brother may do the same.

In art, one of the first secrets of success is simplicity, and simplicity waits upon sacrifice. Art is less than nature, and its best examples leaves something to suggestion. Photography, on the other hand, is emphatic everywhere. In its best examples, a subject may be so arranged and lighted that what is begun positively is carried by suggestion through undertones to shadow, contrast being followed up by association.

The purposes for which photography may be specialised are unlimited. But if one class of subject be sought at every opportunity, without ignoring the range outside his speciality, the amateur photographer will make for himself a purpose whose ultimate value he has no present means of gauging.

To enumerate a few directions in which he may seek to excel, the following may be mentioned. Each capable of endless sub-division:—Scientific Research, Human Nature, Ethnology, Animal Sociology, Landscape, Architecture and Archaeology, Still Life, The Social Circle.

A comparison between the artist and photographer at work will be useful. The former is most frequently a nervous worker. The latter must be a deliberate one. Each must seize an opportunity in his own way.

If then, to begin with, the photographer will bear in mind some of the maxims of the artist, his purpose would be the better upheld by a certain emphasis in his pictures.

Simplicity and sacrifice have already been mentioned.

To make everything in a picture equally important, is to make it utterly feeble. The artist has the power of elision. The photographer has to provide a compromise. Suggestion is the art of compromise. A part doing duty for the whole.

Contrast gives emphasis, it has also to do with lines or forms crossing each other. It is strongest in the right angle and wanting in parallel lines.

Important points in a sky line should be carefully studied, outlines standing clear of each other, and not running in nearly contiguous lines. These repetitions enfeeble a picture. Compare the pulsating effect of a papered wall when the light on it is concentrated to a particular area, and the rest more or less in comparative shadow. With the same subject, in open daylight, you have simply a pattern.

Balance should govern masses and keep them within the precincts of harmony. It regulates proportion, which, in its turn, lends itself to beauty.

The faculty of placing an artistic mean between two or more existing elements, constitutes much of the art sense of the artist.

Figures or objects placed at the cardinal points of a picture—said to be the thirds, fifths, and sevenths—acquire emphasis.

Of light and shade, it would be impossible to speak within the scope of a paper like this, but a contrasted instance may go some way in explaining extremes.

A single portrait subject under a bright sky. A photograph taken without any attempt to regulate the light will be flat and insipid.

Take, again, the same sky and the same sitter, but interpose between them a translucent material like sheeting with an oval opening near the face, continued on the lower side by a lunette of muslin. The stronger beam of light coming through the opening is followed by a feeble light coming through the finer textured muslin, while the diffused light of the whole sheet supports this.

The intenser light is so directed on the face that it shall focus over the nearer eyebrow. We now have the device adopted by all the leading painters, but more emphatically by Murillo and Velasquez; Rembrandt, Rubens, and Vandyk.

Between the two extremes cited there is an infinite variety. In dealing with the lighting of a subject, let but intention exist and its success will be the index of its fulfilment.

The last element I shall speak of is mystery. The undefined but unmistakable atmosphere which enfolds the indescribable entanglement of mingling textures fill one with a sense of mystery. The artist who would paint the moods of nature must penetrate its secret.

The photographer may revel in this depicting of mystery if he but understand it and feel its presence.

My last word will be the master-key of all art canons—the one grain of salt with all the dry pabulum. You will forgive its triteness and its want of novelty—"Art it is that Art conceals."

S. E. CADDY.

DRYING THE BALAGNY FILMS.

THE Balagny films are so popular in Paris because they have no grain, require no oiling when finished, and are worked like ordinary dry plates, except that they must in all cases be alumed and afterwards dried by alcohol. Much about their manipulation has been published by M. Balagny, who makes them by a semi-secret process. It is not impossible that they consist of a layer of emulsion, followed by a layer of regulated thickness of tough collodion, followed again by a second layer of the same emulsion. The collodion in the middle might prevent their expansion in aqueous liquids, whilst the emulsion on both sides of the collodion might prevent their curling when wetted, the tension on both sides of the collodion being then equal. Possibly, also, they may consist of a layer of emulsion between two films of porous collodion. They appear to have been stripped from glass plates, one side of the film having a better surface than the other. Here is

what M. Balagny says in *Le Moniteur de la Photographie* about the final drying of negatives upon his films:—

After they are taken out of the washing waters, in which they should be left at least two or three hours, during which the water is changed five or six times, they are placed in thick blotting-paper to remove all moisture possible; then they are placed, image side downwards, in the following bath:—

Strong alcohol	500 c. c.
Glycerine	50 „

In a new bath, that is to say in one in which at least twenty proofs have not been immersed, the proofs should not be allowed to remain more than three or four minutes at the outside; the surface of the film tends to adhere firmly to the bottom of the bath, but when the bath solution is old it is much better for working purposes, and then the negatives may remain in it for at least ten minutes.

When the bath solution decreases, more alcohol, containing ten per cent. of glycerine, is added, to comply with the terms of the foregoing formula. It is necessary that the bath should have a specific gravity of about 75° at most, because a strong alcohol bath has a more powerful drying effect than a weak one, which will act more slowly. A porcelain or glass dish should be used to hold the alcoholic mixture.

The negatives are taken from the bath one by one and laid upon each other, image side downwards, upon a large sheet of glass; one negative should project over the end of the other to the extent of half a centimetre. The last one is to be covered with a sheet of indiarubber, then, with a gelatine roller, all the proofs are rolled and pressed, to squeeze out the liquid as much as possible. The indiarubber sheet is then raised and replaced by a sheet of blotting-paper, the roller is passed over it, and the uppermost film still further dried; to dry it more completely, take it up by a corner and place it between two dry sheets of thick blotting-paper, over which the roller is then again passed. In rolling the negatives a truly flat surface is requisite for their support; a table, a sheet of glass, or the top of a marble mantelpiece will answer the purpose. This first negative is left in its blotting-paper covering, then all the other negatives are treated in turn in the same way, until a collection is acquired of all the films between leaves of blotting-paper. They are then left to finally dry in a quantity of thick blotting-paper, in which their position is frequently changed, so that they shall not rest too long between two damp sheets.

When they do not feel damp when touched they may be said to be dry; they then have to be flattened out, which is done by placing them for a time between the leaves of an album of thick dry blotting-paper. Afterwards they are stored in a box. If in the course of these drying operations the back of the film loses some of its brilliancy of surface, the dullness can be entirely removed by means of a little absolute alcohol, which will restore its polish and give the film a good appearance.

Such are M. Balagny's instructions. Probably such films might be rendered waterproof by the solution of gold size recommended for varnishing negatives by Mr. W. M. Ashman, but it is necessary that the gold size should be pure and not contain the common adulteration of resin; in the latter case the film will be tacky. If this varnish be made with too large a proportion of gold size, it will also be tacky. Balloon manufacturers usually make their own gold size for varnishing the balloon, to guard against the carelessness of makers who turn it out in the way of trade to be used for less delicate purposes. Some weeks ago the *English Mechanic* gave detailed instructions how to boil down linseed oil so that it shall be fit for varnishing balloons. The gelatine roller mentioned by M. Balagny is doubtless of the kind in common use by letterpress printers.

RECOLLECTIONS OF EARLY DAYS IN PHOTOGRAPHY.

[This is a new and revised version of the *Recollections of Early Days in Photography* by our much-esteemed veteran friend Mr. J. Solomon now residing in New York, sent to us by the author. They were originally written for a contemporary in New York in which they appeared. The errors in the original edition have been carefully eliminated.—ED.]

INTRODUCTION.

THE discovery of fixing shadows is another advance in scientific knowledge obtained by men of the nineteenth century. It had been observed, even as early as in the days of the Ptolemies, that if a hole or small crevice occurred in the wall facing a landscape or seashore, when the closet was closed and dark, the light penetrated the hole or crack, and the shadow from without was reflected upside down on the wall opposite to the opening in the wall. Alchemists had observed that such images could be impressed on sheets impregnated by certain salts of silver on which light exercised a darkening influence. The power of steam had also been observed, and a small toy was made, in those ancient days, showing its power. The magnetic attraction of amber, too, was observed, and it was called electron, from which

originated the term electricity. Yet, from these ancient times to the seventeenth century, no advance or application of these powerful forces in nature for the use of mankind were put into effect. Now the dark clouds which obscured the light of freedom from the middle ages are passing away, and we are nearing the threshold of great results for the general welfare of mankind.

RECOLLECTIONS.

In the summer of 1839, all Paris was excited on hearing that one of the greatest discoveries ever made by man was made by a Frenchman. M. Arago, the great astronomer, informed his fellow academicians that the report was a fact, having been made certain by being admitted into the secret by the discoverer, M. Daguerre, the well-known artist in scenic, dioramic, and panoramic pictures. The great discovery was, that the sun's shadows, as they were seen on the screen of a camera obscura, could be fixed on a surface and handled the same as a picture made by hand in the ordinary way. Another member of the Academy recommended that, for the honour of France, the secret should be purchased by the Government and given to the world. The king, Louis Philippe, supported the proposition, and M. Daguerre was made an officer of the Legion of Honour, and well paid for his discovery.

Either about the same time, or shortly after the negotiation for the purchase of his secret, he went to England, and from the aid given him in London by a Frenchman named Claudet was enabled to obtain an English patent.

The English patent was placed in the hands of an agent to sell, and, although the French Government purchased the secret to give to the world, the English patent debarred the gift to the English nation. But it was found that others were in the field besides M. Daguerre, searching to fix the shadows as seen through a camera obscura, and the Government, I believe, gave a pension to both Daguerre and to Isidore Niepce; continuing its favours to Niepce de St. Victor, a nephew of M. Niepce, who was in the army, but, in his leisure, pursuing the researches of his uncle. He was granted a suite of rooms in the Palace of the Luxembourg, to continue his researches on fixing the colours in the images. I have seen one of these pictures, which was a large bird, with brilliant, various coloured feathers. The picture was on silver plate, about whole size ($6\frac{1}{2} \times 8\frac{1}{2}$ inches), and the colours, although true, were not pleasing, from having a Dutch metal, dazzling effect; and also, it was only to be seen in a darkened room by the light of a small candle. It was rumoured that Daguerre had made with the elder Niepce a tacit agreement that each should inform the other of any progress or discovery, and that they should share in the success if the object sought to be obtained was gained, but that Daguerre, who had received many hints from Niepce's studies, had not informed Niepce of his discovery. No doubt this rumour was a libel on Daguerre.

After Daguerre obtained his patent in England, he gave a written authority to Mr. Claudet to take pictures in London, without requiring any permission from the purchaser of the patent; and when portraiture was obtained on silvered plates, the purchaser of the patent, Henry Beard, a coal merchant, opened a studio in the Polytechnic Exhibition Building, at the top end of Regent-street, and Mr. Claudet opened a studio in the corner building, at the bottom of Regent-street. Beard gained more than 100,000*l.* from his purchase of the patent, and at the same time Niepce and Daguerre were pursuing their researches to obtain the coloured images as seen in the camera obscura. Others, in different countries, were searching to obtain the means of fixing them, and amongst them was Mr. Fox Talbot, a descendant of an English noble family. He was a member of the Royal Society, and discovered the means of fixing the shadows on paper, and he was probably the first who obtained copies printed from the first picture taken. Mr. Talbot also patented his discovery, and the honourable position of Mr. Talbot as member of the Royal Society caused many sneers and reproaches towards him, and the public considered that he should have freely given it to the English people, as he was rich in means and high in descent.

About the year 1840, I purchased, in company with my brother-in-law, a portrait artist and a painter of landscapes, a set of Daguerreotype apparatus from a well-known large artists' colour store, then in the Rue Coque St. Honoré, which street does no longer exist in Paris. We set out to follow, as near as possible, the written published methods to obtain a picture, but failed. I remember that to obtain the vapour of iodine on the silver plate, either before the mercury was on it or after, I placed the iodine in a small dish in the corner of a room, and held the plate over it for a very tiresome time and obtained nothing but smudges instead of pictures; so I abandoned the whole thing. The two first pictures shown to the general public was from the store of Susse Frères, the noted artistic store in the Place de la Bourse, and these two were pictures of the same object—

a row of houses; and I think the pictures were on plates about 7 x 4 or 5. The pictures were taken from the same spot, and every brick, stone, crack, &c., appearing so microscopically exact, the lookers-on were filled with astonishment. Prophets foretold that artists in landscape pictures would be no longer required; but Daguerre expressed his opinion that the invention would never be useful for portraiture on account of the time required—fifteen or more minutes—to obtain a picture. The lens employed was a simple achromatic meniscus; but some time afterwards, Buron, the largest optical manufacturer in Paris, produced a double combination lens for obtaining quicker results. From that time attempts for obtaining portraiture began.

I was an inhabitant of Paris for some years and then went to London to obtain orders for French manufactured articles, particularly opera glasses, and represented the manufacturer of superior opera glasses in Paris. Palmer, a druggist, who also kept a furniture store and articles of science in Newgate-street, London, gave me orders for various articles, amongst which was a quarter portrait lens, and I remember the consternation I had. One of the assistants in unscrewing and rescrewing had changed the lenses, but the next day the error was discovered.

Amongst the sundries was a bottle containing six or eight pounds of the new chemical, hyposulphite of soda. I found the manufacturer and purchased four kilos, a little over eight pounds English. I did not know the exact price, but Palmer's people had given me the liberty to pay whatever the French chemist charged. They would pay, if even beyond the English manufacturers' price in England, so I quite fulfilled their order on all they wished me to purchase for them, and I left France for England about three months after. When I arrived in London I paid duty on what I brought with me, and charged Palmer eight shillings per pound for the hypo. They then made a grand fuss and reduced their retail price to what the wholesale manufacturers were charging for it wholesale. Then the article began to find its use in the manufacture of paper, and Newcastle-on-Tyne manufacturers made it in tons, so that it was sold retail for ten shillings per barrel of 100 pounds weight.

The making of Daguerreotype portraits was an extensive occupation for many, and Henry Beard having speculated away all his immense gains, had no means of renewing the last payment of 100% on the patent, so it fell into the public's hands, and thousands of people commenced taking Daguerreotype pictures. The requirements in materials was very varied, and some very expensive, such as deep glass dishes, two of which were in one box, shut out from all light, on the top of which the portrait was placed to receive the iodine and the other fumes. Small doors at the side with looking-glass were opened to obtain a glimpse from the top of what was going on. The Daguerreotype plate in England was manufactured by a company called the Soho Plate Company, Birmingham, and in Paris a firm commenced to manufacture the plate, and erected steam and rolling mills. The name of the firm was Alexis Gaudin & Co., and they also commenced manufacturing every requisite required in the art, and although the duty in England was twenty-five per cent., and other expenses of transit, &c., nearly ten per cent. extra, yet the French house could pay the duty and expenses and quite undersell the English manufacturers.

On my journeys between France and England, the noted optician, Andrew Ross, and his son, used to request me to bring them specimens of the then advanced position of photography on paper, and for a picture on paper about the size of the album portrait I obtained from this firm ten shillings, being very careful only to fulfil such orders for houses of eminence, because Talbot pursued by law any one infringing his patent. Amongst other photographers in Paris, an artistic designer for lithographic printing prepared a gelatine negative on glass, and one order from Willet, an optician, was to purchase a prepared gelatine glass to cost ten francs, but, of course, not being properly preserved from light, it was useless for obtaining a portrait.

J. SOLOMON.

(To be continued.)

EXHIBITION OF THE AMATEUR PHOTOGRAPHIC ASSOCIATION OF VICTORIA.

THE Fourth Annual Exhibition of this Association was opened at the Royal Society's Hall, Melbourne, on July 19. The display of exhibits was large and varied, and showed to great advantage the progress made by the Association during the last twelve months.

Among printing processes on paper, silver prints, as a matter of course, carried off the palm for numbers, but there were represented also carbon, gelatino-bromide, platinotype, and gelatino-chloride processes. Several window transparencies on gelatino-bromide, also stereoscopic and lantern transparencies on bromo-chloride plates, were shown. Stereoscopic photography is pursued by a large number of the members of the Association,

and the results which they produce create considerable interest amongst those members who have not yet taken up this delightful branch of work and also amongst the general public, the marvellous power of the stereoscope being a thing almost unknown by the "rising generation." Mr. J. Musgrove's fine set of stereoscopic transparencies, exhibited in the revolving stereoscope, together with a revolving frame of his own invention, which shows the negative, with silver and carbon prints and transparencies from the same side by side, made his table a centre of attraction each evening. Mr. E. C. Bell occupied another table, upon which he had mounted eight stereoscopes, supplied with over three hundred stereographs. Messrs. E. A. Walker and J. H. Harvey also exhibited a collection of stereoscopic slides.

A notable feature of the Exhibition was the very small quantity of instantaneous shutter work shown, only three or four members exhibiting. This may be taken as a natural consequence of the state of things which existed a few years ago, when all amateurs (save a few of the steady ones) thought that a snap shot should be taken at everything. Many have become alive to the fact that instantaneous work—of a sort—is as easy of accomplishment by the beginner as by the experienced practitioner, and have, therefore, abandoned the practice of advertising the plate makers by wonderful tales of the exceedingly short exposures by which their work was produced.

The principal instantaneous exhibit was a set of their famous yacht studies, kindly lent by Messrs. G. West & Sons, of England; these were universally admired, and formed one of the gems of the Exhibition.

The leading enlargements of portrait and landscape work shown were by Mr. J. Musgrove; these were printed in carbon, having been enlarged from stereoscopic size to about 15 x 12 inches. A set of views taken in the "Zoo" attracted much attention, being the work of Miss A. J. Cooper, the only lady member of the Association.

The chief architectural work shown was produced by Messrs. F. A. Kernot, J. Mulvany, and J. H. Harvey. Messrs. Mulvany and Kernot showed various buildings about Melbourne and suburbs; Mr. Harvey having sent in a frame containing similar interior views of the Melbourne Parliament Houses to those he showed last year, supplemented with several interiors of this stately building which he has obtained since; he also showed other whole-plate views of public buildings in various parts of the colony, together with a frame illustrating the scenery in and around Sydney.

Portrait work was poorly represented, although a few excellent specimens were shown here and there. Mr. J. Lang's landscapes, several of which were printed in platinotype, are worthy of mention. He had printed duplicates of many of them in silver, thus affording an interesting study, as the results were hung side by side. Amongst landscapes, a fine set, kindly presented to the Association by Messrs. Jas. Swift & Sons, of London, illustrated work done by lenses of their manufacture. This firm also sent a print of the famous enlargement of the proboscis of the blow-fly, executed by Mr. M. J. Swift.

The Philadelphia Amateur Photographic Club showed a number of silver prints of all sizes, many of them being of great beauty as artistic studies as well as technically faultless.

A large collection of prints and lantern slides was sent by the Queensland Photographic Association, illustrating life and scenery in the progressive northern colony.

The lanterns of the Association, under the charge of Mr. J. H. Harvey, were located in an adjoining room, and at intervals during each evening a number of slides were exhibited, illustrated by the limelight. The photographic material-importing houses sent good assortments of novelties and interesting apparatus, which were shown in a third room.

It was generally agreed that the Exhibition was the best yet held by the Association, both by reason of the quantity and quality of the work shown.

In the competitions the awards were made as follows:—Large landscapes: 1, J. H. Mulvany; 2, J. Lang. Groups and portraits: 1, G. F. Fullarton. Architecture: 1, J. H. Harvey; 2, F. A. Kernot. Small landscapes: 1, C. Harper; 2, G. F. Fullarton; 3, J. H. Mulvany. Enlargements: 1, J. A. Musgrove.

Efforts have been made on two or three occasions to induce British Amateur Associations to forward work to the exhibitions of this Society, but have failed. American Associations which have been invited have generally responded. What's the reason?

PROFESSOR DEWAR ON LIGHT AND ITS ACTION.

I.

DURING the last Royal Institution Session, Professor Dewar delivered a considerable number of experimental lectures, in the course of which he occasionally had much to say upon light and its chemical action, which portions of his discourses are here selected and summarised.

In speaking of light as an analytical agent, he said that it is particularly prone to set up changes in organic bodies. Wollaston in early times discovered the action of light upon gum guaiacum, and it has since been found that guaiaconic acid derived from the gum is more sensitive; some

of this acid dissolved in collodion he applied to the surface of paper, and showed that by half a minute's exposure to the light from a powerful arc lamp the film became of a beautiful blue colour, as deep as the hue produced by ordinary iron blue printing processes. The chemical change set up in this complex acid by light is not yet understood, but Professor Wörter has recently discovered an organic substance, tetramethyldiamine, which is sensitive to light, and the chemical constitution of which is known. This new body is also very sensitive to the action of ozone, which turns it purple; even sulphate of copper will in a limited time turn it a rich purple colour by oxidation; ether poured upon it in the presence of light turns it purple. Tetramethyldiamine is one of the coal tar colours easily acted upon by light, and is probably the first of a large series of bodies which all contain methyl, and all are likely to be sensitive to light; the presence of methyl seems in some way to be necessary to the action. In dilute solution tetramethyldiamine is quite colourless when spread upon paper; light acts less rapidly upon the paper so prepared than it does upon paper prepared with guaiaconic acid. The sample of tetramethyldiamine used by Professor Dewar had been obtained by him from Dr. Schuchardt, of Gorlitz, Germany.

In relation to recent speculations about the possible decomposition of the chemical elements, Professor Dewar said that Professor Stas, of Brussels, has by urging refinements in preparation, obtained elements of more purity than has anyone else; he has, for instance, prepared salts of potassium so pure, that they will give no sodium line in the spectrum when placed in an ordinary flame. In every way he tried to decompose or transmute the pure elements, but all the attempts ended in absolute failure.

A beautiful red light was produced by Professor Dewar by means of chloride of lithium in the flame of a Bunsen burner, and he said that the particular red rays given out by a lithium flame are just those which are absorbed with most avidity by the chlorophyll in the leaves of plants. Chlorophyll cuts off the violet rays of the spectrum, and has a remarkable absorption band in the low red; a bottle of solution of chlorophyll reflects red, and recent discoveries have proved that the maximum effect on vegetation comes from the low red rays, not, as Draper thought, from the yellow. He added that in 1864, in a lecture at the Royal Institution, Helmholtz stated that comparing the production of carbon by an area of cultivated land with the whole energy of sunlight expended during its growth, he calculated that about the $\frac{1}{1000}$ part is conserved in an available form, and may be obtained from its combustion. This estimate is, strictly speaking, the mean agricultural efficiency of a given area of land cultivated as forest; and considering that active growth only takes place during five months in the year, we may safely adopt $\frac{1}{1000}$ part of the total energy of sunlight as a fair value of the conserved power on a given area of the earth's surface in this latitude during the course of the summer. Professor Dewar calculated that if it were attempted to balance by vegetable growth the one hundred millions of tons now extracted annually by Great Britain from her coalfields, it would be necessary to cultivate twenty times the area of our coalfields for the purpose, and the area would exceed that of the whole of the United Kingdom of Great Britain and Ireland. If the whole of these islands were covered for 20,000 years with forests conserving energy from the sun's rays, the result would equal the conserved solar energy of our coalfields.

De la Hire in 1690, and Bonnet in 1754, showed that green plants when immersed in water and exposed to sunlight gave off bubbles of gas, and Ingenhous, in 1779, showed that green plants convert a considerable portion of the air around them into carbonic acid when not exposed to light; he also showed that the absorption of carbonic acid by the plant is due to the light and not to the heat of the sun. Senebier, who worked at the subject from about 1779 to 1804, discovered that the carbonic acid in the air is decomposed by vegetables under the influence of solar light, and that the red rays cause the production of more oxygen than do the violet; he also observed the different heating powers of the rays of the solar spectrum; he investigated the action of light on the colouring matter of flowers and the colouration of fruits. Boussingault began his experiments in 1840. In 1868 he published that leaves exposed to the sun in pure carbonic acid do not decompose it, whereas rapid decomposition takes place when the acid is diluted with atmospheric air, nitrogen, carbonic oxide, hydrogen, or marsh gas. Leaves become asphyxiated when kept in the dark in gaseous atmospheres free from oxygen, and then have no power of decomposing carbonic acid in the sunlight. Essential oils retard the action of the leaf. The vapour of mercury rapidly kills plants, as discovered by Dutch philosophers in 1797. Boussingault found that the upper surfaces of thick leaves decompose more carbonic acid than the under; in the sun the ratio is as four to one, in the shade as two to one. On an average one square yard of leaf surface, acting during a day of twelve hours, decomposes 306 cubic inches of carbonic acid, or $1\frac{1}{2}$ gallon, yielding nearly the same volume of oxygen. In 1869 he found that the luminosity of phosphorus could be used as a rapid and delicate test of the absorption of carbonic acid by the leaf; this test enabled him to prove that leaves decompose carbonic acid immediately on exposure to sunlight, and cease their action instantly in darkness; they effect no decomposition before the presence of chlorophyll can be detected. Experiments by Draper in 1844, supplemented by Sachs and Pfeffer at a later date, proved that

only those rays of the sun which are visible to the eye have the power of decomposing carbonic acid, and announced that those which are brightest to the eye, namely, the yellow rays, are alone as efficacious for this particular purpose as all the others put together. Experiments by Timiriazeff prove that the portion of the spectrum for which chlorophyll has a specially selective absorption is most efficient in the decomposition of carbonic acid. Sachs has recently discovered that the ultra violet rays of the sun are necessary for the production of flowers; when all the ultra violet rays are arrested by a solution of sulphate of quinine, flowering will not take place under the influence of the remainder of the light transmitted, or at most but one meagre flower has been so obtained in the experiments not long since concluded.

Many of the points stated in the last paragraph Professor Dewar demonstrated by experiment. His method of stopping the transpiration of one side of a leaf to see what work was performed by the other side, was to coat it with collodion. He said that it might be asked why leaves did so much work with so small a proportion of carbonic acid as that in the atmosphere. The question was not easy to answer, but it was a fact that sometimes chemical actions would go on best at low pressure; he illustrated this by taking a flask coated inside with phosphorus, and this was not luminous at the ordinary pressure of the atmosphere; when, however, he reduced the pressure inside the flask by means of a few strokes of the air-pump, the phosphorescent coating began to glow in the dark. The amount of carbonic acid given off by animals and fires is not sufficient to sustain the vegetation of the world; most of the necessary carbonic acid comes from sea water, the bicarbonates in which give off one portion of their carbonic acid very freely. Thus the balance is preserved.

He proved that seeds give out feeble heat when germinating by means of some peas which were soaking in water; by the aid of a very delicate thermo-pile it was demonstrated that the temperature of the water was slightly higher than that of the surrounding air. He exhibited some mustard and cress which he had been growing in darkness; they had grown to greater dimensions than if they had been exposed to light, but they were yellow all over, no chlorophyll had been formed, and the growth had all taken place at the expense of the seed; it was a case of vegetables living upon their own vitals, so to speak.

Among substances which transmit the photographic ultra violet rays of the spectrum, and to which glass is opaque, are rock-salt, quartz, extremely thin films of silver, iodine vapour, water, chrome alum, and permanganate of potash. Of these the silver film, chrome alum, iodine vapour, and solution of permanganate of potash in sufficient thickness, cut off the visible rays.

In a true or diffraction spectrum there is much green; in an ordinary spectrum there is little green, the rays at that end being so little spread out in proportion to the blue end. The following is the result of experiments as to the relative intensity of red and green rays from incandescent platinum:—

LIGHT RADIATION OF PLATINUM.

Temperature, Deg. C.	Luminous Intensity.	
	Red Rays.	Green Rays.
954	1.0	1.0
1045	8.27	3.64
1500	154.00	219.00
1775	507.00	809.00

Thus highly incandescent platinum is relatively rich in green rays.

The following are results of experiments as to the amount of luminosity given by the whole of the sky, as compared with the luminosity of the sun at the same zenith distance;—

Place.	Sun.	Sky.	Ratio.
Manchester	43	140	0.31
Kew	150	162	0.93
Heidelberg	263	174	1.51
Pará	163	136	1.00
Paris	222	501	0.44

Professor Dewar stated that the average height of clouds is: Cirrus, $4\frac{1}{2}$ miles; cirro-cumulus, 4 miles; alto-cumulus, $2\frac{1}{2}$ miles; false cirrus, 2 miles; cumulus, 1 mile.

ALVAN CLARK.

[The following has been sent to us by an American friend, but we are unaware to which source to credit it.—Ed.]

By the death of Alvan Clark, at Cambridge (Mass.), of an abdominal disease, America loses a most remarkable man, known throughout the world as the manufacturer of enormous telescopes, famed not only for their size but for their extraordinary accuracy. He was born at Ashfield (Mass.), in March, 1804. His father was a farmer, and young Alvan worked in the fields while a boy and had few opportunities for study. Very early in life his artistic instinct led him to devote much of his spare time to engraving and drawing. At twenty-two years of age he obtained a situation as a calico-printer in a Lowell mill, working at this business for nine years, when he established himself as a portrait painter

in Boston. It was not until he was more than forty years old that he became interested in the study of optics and the construction of telescopes. He thus explains the story of its inception:—"My son, Alvan G. Clark, was at Andover studying to be an engineer. His mind seemed to be absorbed in telescopes. I was a portrait painter then, and I began to study mechanics and astronomy so as to instruct my boy. We experimented together and succeeded in making a reflecting telescope. One of the Cambridge professors was much pleased with some instruments we made, and when we suggested to him that we would like to manufacture improved instruments he gave us great encouragement and we went ahead."

Mr. Clark and his two sons gave up everything else, and in 1846 commenced the manufacture of telescopes at Cambridge (Mass.). The first important recognition came from England. Rev. W. R. Dawes, celebrated for his measurement of double stars, learned that Mr. Clark was constructing instruments of superior purity and power, and ordered a glass, which was furnished in 1853. The performance of this glass excited the admiration of English astronomers, and Mr. Clark found himself suddenly famous. Orders began to come rapidly in also from among his own countrymen, and from that time he was looked upon as one of the few men competent to supply a perfect object glass. In 1860 the University of Mississippi ordered a telescope of Mr. Clark with an aperture of eighteen inches, which was three inches larger than any made at that time. Before it was completed the war broke out, and the contracting party did not take it. It was afterwards sold to the Astronomical Society of Chicago, and was mounted in 1863. It was with this instrument that Alvan G. Clark, Mr. Clark's son, in 1862 discovered the companion of Sirius, receiving the award of the Lalande medal from the French Academy of Sciences. He was given one hundred dollars in gold, however, preferring that sum to the medal.

During the war the Clarks were kept busy manufacturing field glasses for use in the Federal Army. At the time the American observing party went West to view the transit of Venus the Clarks were called upon to supply a heliostat to be used in photographing the transit. The first telescopes made by the Clarks were six inches in aperture and of exquisite definition. The firm confined themselves exclusively to the manufacture of refracting telescopes, and without losing in precision they successively made object glasses of $8\frac{1}{2}$, 9 $\frac{1}{2}$, 12, 15 $\frac{1}{2}$, 18 $\frac{1}{2}$, 23 and 26 inches.

The telescope for which they received the most credit is that at the Naval Observatory at Washington. In 1870 Congress passed a Bill authorising that a contract be made with the Clarks for a refracting telescope, to be the largest in existence. The size was placed at twenty-six inches aperture, and work was commenced upon it in January, 1871. In 1872 the glass seemed absolutely perfect, and a microscopic photograph illegible to the naked eye could be read through it at a distance of four hundred feet. More work, however, was put upon it, and it was finally mounted in 1873. "The figuring of this glass is almost perfect," says Professor Newcomb, its custodian, "its principal defects arising from the secondary aberration, which is inseparable from a large refractor." Soon after the completion of this telescope the order was received for the McCormick telescope, which was to be its duplicate in every respect.

The late Alvan Clark made many discoveries. He also invented a double eyepiece, and an ingenious and valuable method of measuring small celestial arcs from three to sixty seconds. Among other of the great works of the Clarks may be mentioned the magnificent telescope for Princetown College, and also one of vast importance bequeathed by Mr. Lick, a wealthy Californian, for an observatory in the Golden State. Alvan G. Clark is now in Europe seeking materials for filling the order for this Pacific Coast institution, which is intended to be in its equipment not surpassed by any in the world. Mr. Clark received the degree of M.A. from Harvard, Chicago, Princetown, and Amherst, and other honours have been showered upon him by American and foreign scientific bodies. His long life has uniformly been one of singular seclusion and modesty.

FRENCH REWARDS FOR PHOTOGRAPHIC INVENTIONS.

Our correspondent in Paris, Professor Stebbing, has occasionally mentioned in these pages something about the rewards offered in France for certain new photographic discoveries or inventions. As this feature of photography does not exist so largely upon this side of the Channel, we quote the full particulars relating to prizes open at the present time to public competition on the other side of the water. As regards the prize offered by M. Davanne, it may be remarked that the man who could win it would probably find it much more profitable to use his knowledge as a trade secret. Competition for two of these prizes, being international, is open to our readers.

PRIZE OF THE MINISTER OF PUBLIC INSTRUCTION.

A prize of 2000 francs (80*l.*), offered by the Minister of Public Instruction, and put up for competition, for photographic objectives principally intended for the use of travellers.

The instruments sent in must be made in France by constructors living in France.

The competitors must send in two classes of lenses.

The one panoramic, embracing an angle of at least 100°.

The other constructed for producing negatives of not so great an angle. This class should unite the qualities of rectilinearity, flatness of field, sharpness upon different planes, equality of luminous field, and intensity of illumination sufficient to produce rapid impressions whenever necessary.

The instruments sent in should be constructed to cover plates of the dimension of 18 x 24 cm. Those which can be used for copying and the obtaining of human types should have no longer focal length than 0.25 m. or 0.30 m., and give sharply and without deformation a head of 0.03 m. at least, with a time of exposure which, with wet collodion, would not exceed four seconds in the shade.

The size and weight of these instruments should be as limited as possible, and the mounting simple. The diaphragms, if more than one, should be attached to each other so that they cannot be separately lost. Their price should be within the limits of the prices usually accepted for good lenses.

THE GAILLARD PRIZE.

A prize of 500 francs (20*l.*), offered by M. Gaillard, will be given to the discoverer of a new process for printing positives, or of a notable improvement in the method hitherto in use.

The process which gains the prize must fulfil the following conditions:—

1. Rapidity of exposure, whether it be to solar or artificial light.
2. Uniformity of manipulation and in the results obtained.
3. The proofs should have agreeable tones under the control of the will of the operator.

Between different processes fulfilling these conditions, preference will be given to those which promise the most permanent results.

This competition is international. The Presidents and Vice-Presidents of the Photographique Society of France, and of its Committee of Administration, are excluded from participating in it.

The parcels sent in by the competitors should include—

1. A sealed enclosure containing a description of the process, the formulæ, the manipulations, in a word, all the information necessary for the complete working of the process.

2. Several photographs produced by the indicated means.

The opening of the sealed envelopes will be made in the presence of the competitors or their delegates, or fifteen days after a written notice has been sent from the Secretary of the Commission.

The competitors shall give a demonstration before the Commission, or, if they are unable to be present, they shall abide by the results of the trials which the Commission may make, or cause to be made before it.

The report of the Commission shall be made within one month of the conclusion of the last trial.

Particulars of the successful process, and of exact information in relation thereto obtained by the Commission, shall be published at the same time that it gives its decision, and will become public property.

THE DAYANNE PRIZE.

A prize of one thousand francs (40*l.*) will be given to the discoverer of a process for obtaining negatives fulfilling the following conditions:—

1. Facility of preparation of the sensitive surface.
2. Sensitiveness and keeping qualities comparable with those of preparations actually in use.
3. The negatives obtained shall approximate in fineness and permanence to those obtained by older preparations.

The parcel forwarded should contain—

1. Sealed information describing the process in all its details.
2. The negatives obtained and positive proofs taken from them.

The opening of the sealed letters will take place before the Commission which has the duty of judging, and in the presence of the competitors.

The competitors shall demonstrate before the Commission, or, if they cannot be present, shall abide by the results of trials made by it.

Particulars about the successful process, and exact information about it, will be published at the same time that the decision of the Commission is made known, and will become public property.

The competition is international.

CONDITIONS COMMON TO THE THREE COMPETITIONS.

The time for competition will be closed on the 31st December, 1888. Parcels should be received not later than that date at the offices of the Society, 20, Rue Louis-le-Grand, Paris.

The Commissioners to form the jury will be nominated by the Society at its December meeting in 1888. Competitors cannot serve on the jury. — *Bulletin de la Société Française de Photographie.*

Our Editorial Table.

MESSRS. MARION & Co., Soho-square, have issued a "Universal Ten per cent. Developing Set" which they correctly say will prove a great boon to all amateurs. On opening the neat case in which the set is contained, we find six glass-stoppered bottles and two graduate measures. Three of the bottles contain solutions respectively of pyrogallie acid, bromide of potassium, and ammonia, all of them

being ten per cent. solutions—the other three bottles are for mixing.

The use of these solutions will be readily understood from the following directions which accompany the set:—

“On each bottle of the ten-ounce solution is a list of the leading plates, and against each the correct formula for development expressed in minims, so that our ten per cent. solution will serve, not only for our own Britannia plates, but for most others. The directions for use are simple—take as an instance to make up a developer for the Britannia plates. On the bottle of pyro against the word Britannia will be found twenty minims. This signifies pour into the minim measure the pyro solution up to twenty; after measuring it pour it into the larger glass measure, perform the same operation for the bromide, and then for the ammonia, taking care only to measure out the quantity of minims marked on each bottle against the word Britannia. Of course, after measuring, each solution is poured into the larger glass measure. Now make it up to one ounce by adding water. If two, three, or four ounces of developer are wanted, of course the minims must be increased in like proportions, viz. twice, thrice, or four times also. If it should be desired to make up stock solutions in the two ten-ounce mixing bottles, and in developing to take equal parts of each, the minims that are given for one ounce of the different solutions must be multiplied by twenty. Thus, in the Britannia formula, put of pyro solution ($20 \text{ minims} \times 20 =$) 400 minims into one of the bottles; and of bromide ammonia ($22\frac{1}{2} \times 20 =$) 450 minims into the same bottle, then make up to ten ounces with water. In the other bottle would be the ammonia ($45 \text{ minims} \times 20 =$) 900 minims and make up to ten ounces with water. For developing take equal quantity of solution from the two bottles, and so for each make of plates according to formulas given on bottle.”

Of the various appliances which have been introduced to simplify photographic operations to the amateur, Marion's ten per cent. developing set will prove to be very far indeed from the least to be useful, and to receive a glad welcome accordingly.

From H. Senier, Norwood-road, S.E., we have received samples of Wolff's patent mounts, the peculiarity of which consists in the card being coated with gum or other adhesive substance. To mount a print upon such cards, all that is necessary is to lift it from the washing water, remove the superfluous water slightly by blotting-paper, and lay it down in its place upon the mount, afterwards applying pressure.

EN SUITE with the *Bicyclist's Handbook*, which we noticed a few weeks ago, Mr. Henry Sturmey has issued a work of similar character devoted to photography. It consists mainly of a compilation from dealers' catalogues made by W. D. Welford, of Birmingham.

We have received from William Tylar, Birmingham, one of his washing and drying racks. It is made of japanned wire with metal pins, covered with indiarubber, to form the divisions. He also sends us a specimen of his metal printing frames, which is formed on the same general plan as those introduced many years ago by Cubley & Preston, of Sheffield, only theirs had a wooden back, whereas this is formed of rigid metal.

Mr. Tylar also sends us samples of his folding developing trays. These will prove useful, especially to the tourist. They are so constructed as to lie flat, yet by means of suitable folds and clips at the corners they can instantly be formed into trays of all the requisite depths for developing, fixing, and washing negatives. Each has its special use printed legibly on the flap by which it is held when in use, hence confusion cannot arise.

J. T. CHAPMAN, Manchester, has brought out a series of handy books, small in size, but replete with useful information. One of these contains simple instructions for printing, toning, fixing, and finishing photographs on albumenised paper. Another is devoted to modern photographic lenses, with a synopsis of their construction and uses; while a third contains formulæ and directions for developing negatives, transparencies, and opals.

Those who use petroleum (and who does not?) will find a vast amount of sound information concerning it in a pamphlet entitled *Petroleum: Valuable Hints to those who use it*, being a series of articles on the subject by well-known authorities. It is published at 402, Strand, London.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
September 27 ...	Great Britain (Technical)	5A, Pall Mall East.
“ 27 ...	Bolton Club	The Studio, Chancery-lane, Bolton.
“ 27 ...	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
“ 29 ...	Liverpool Amateur	Royal Institution, Colquhoun-street.
“ 29 ...	Oldham	The Lyceum, Oldham.
“ 29 ...	London and Provincial	Mason's Hall, Basinghall-street

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday, September 15, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. William England presided.

The HON. SECRETARY exhibited etchings of places in Edinburgh visited recently by the Photographic Convention, he did not know by whom executed.

Mr. C. H. TRINKS said that in Norway recently he had greatly under estimated the actinic power of the light, so had over exposed most of his plates; his best results were with $\frac{1}{4}$ and drop shutter exposures. In Greece and Turkey he had not found the light so photographically powerful.

Mr. HERBERT STARNES had a friend who had taken views in Norway five years ago, and developed them but a few days ago; the results were all that could be desired.

Mr. S. G. B. WOLLASTON had obtained insufficient density in the high lights when developing plates which had been kept four years after exposure.

Mr. A. COWAN had found that plates grew more sensitive by keeping; they probably would not do so but for the vapour of water in the atmosphere.

Mr. STARNES said that high temperature caused deterioration of plates kept therein for a very long time.

The CHAIRMAN thought that a moderate amount of heat did not injure them.

The HON. SECRETARY exhibited sensitised albumenised paper which had kept good for two years wherever three thicknesses of it had protected the remainder underneath.

Mr. A. MACKIE and Mr. F. A. BRIDGE found ready sensitised paper to work better when kept one or two months.

The CHAIRMAN, to get more vigour with thin negatives, sometimes place them where they would take a whole day to print, and thereby obtained more contrast.

Mr. W. E. DEBENHAM's experience did not support the last statement.

Mr. COWAN thought that comparative experiments on the point should be made.

The CHAIRMAN had found the rule he had stated to hold good in copying also.

Mr. E. CLIFTON had seen experimental results obtained by Mr. George Smith which supported Mr. Debenham's view. Exposures for a longer time to a weaker light gave the same result as shorter exposures to a stronger light, on the principle that the intensity of light varies inversely with the square of the distance.

Mr. A. L. HENDERSON, with several days' exposure upon washed sensitised paper, had obtained vigour and detail which otherwise would not have appeared.

The CHAIRMAN with many wet plate negatives had found that they gave much better prints in the spring than in the winter.

Mr. HENDERSON said that if a piece of sensitised paper were printed in the sun to a certain depth and another piece of the same paper printed in weak light to the same depth they would be of different colours.

Mr. DEBENHAM, assuming the absence of error in the last statement, was not sure that difference of temperature would not have an influence.

Mr. CLIFTON had known heat to change an exposed print from a purple to a red colour.

Mr. W. M. ASHMAN said that there was a distinct difference in colour between photographs printed in a weak and strong light.

Mr. A. P. HIGGINS pointed out that in photography in natural colours difference of illumination produced great differences of result in printing upon chloride of silver.

Mr. ASHMAN had found no practical difference in printing weak negatives in a strong or weak light.

The CHAIRMAN stated that with slow printing bronzing could be obtained in the shadows under weak negatives.

The meeting was then made special, and the following members were elected as the first Committee of Management of the Association:—Messrs. W. M. Ashman, T. Bolas, F. A. Bridge, J. T. Collins, A. Mackie, L. Medland, H. M. Smith, and C. H. Trinks.

Correspondence.

Correspondents should never write on both sides of the paper.

DISCOLOURATION OF PORTRAITS IN OILS.

To the Editors.

GENTLEMEN,—“An Amateur” wishes to know “the circumstances under which portraits in oil (not on photographic base) will become discoloured, as described by ‘Free Lance,’ and the causes that lead to same.” First, I must point out that “Free Lance” never described the discolouring in question. After inquiring about the pictures, he merely was told, “Oh, the faces went all black.” “An Amateur” will understand that it is impossible, and would be, indeed, audacious, to form and put forward a distinct opinion as to what really occasioned the change of the colours in this particular case on such scanty revelation.

Discolouration may arise from smoke of the fireplaces, or from cleaning the rooms by careless hands, who even will rub the pictures over with dirty flannels, &c., or it is caused by the oil in which the colours are ground. One more of the many factors which contribute to blacken or discolour oil paintings is to be found where the second painting was done before the first or ground painting was thoroughly dry, or when the varnishing was practised too soon. The second painting should not be before the preceding painting was allowed to dry, at the least, from three to four months, and any varnishing of the finished picture can only be done with safety after an elapse of twelve to eighteen months. The oils used should be bleached for at least five years, and the varnish at the least for ten years.

Any picture gallery will show to “An Amateur” decayed, damaged, and blackened conditions of oil painting; but “how to restore them,” I must recommend him to consult some works written upon this subject—for example, such as Field’s *Chromatography*.—I am, yours, &c.,

A PAINTER.

YELLOW STAINS IN THE NEGATIVE.

To the Editors.

GENTLEMEN,—Is it known that sal-ammoniac prevents the yellow stain when using the carbonates?

The following I find to do very well for landscapes:—

Carbonate of soda	15 grains.
Carbonate of potass.....	15 „
Sal-ammoniac	5 „
Bromide of ammonia	1 grain.

I get stains when I add the bromide in a 1-10 solution. I therefore use one ounce water, one grain bromide, and add the concentrated solution.—I am, yours, &c.,
J. C.
Southport.

PRINTS MOUNTED ON GLASS IN OPTICAL CONTACT.

To the Editors.

GENTLEMEN,—What can be the reason—a fair and valid reason—why such a dead set is made against this most beautiful process by exhibition committees, and (if I am rightly informed) by some individual judges, too?

Can any arguments be stated against its use which are strong enough to be unanswerable? A circular has lately been issued by the Dundee Association for an exhibition in February next, in which I notice that “Photographs mounted on glass” will be received for exhibition only, i.e., they are excluded from competition for prizes. Why so? What advantage of an unfair nature can such a method of mounting prints give to any photographs? It appears to be prompted by some unaccountable feeling of jealousy that the print in optical contact with glass should be so beautiful in itself. The process certainly cannot alter the actual quality of a print—if it is first rate in itself as a print before mounting it will still be first rate after attachment to the glass plate, neither more nor less so; and, given a dozen prints by different operators of equal merit as “pictures,” no unfair advantage would accrue to any of them if all are mounted alike in optical contact with glass. But if one operator argues thus, “I do not wish to mount mine in this way, and because I won’t adopt it you shan’t do so and compete against me for prizes,” is a very “dog in the manger” sort of argument.

I maintain that the five following important advantages belong to this process of mounting, and particularly for purposes of framing, whether for public exhibition or not.

(1). It is the best method of all to enable any person to see a photograph correctly, be it good, bad, or indifferent *per se*. The exquisite delicacy of the photographic detail is to some extent lost on paper which is in the

least rough, scratchy, or uneven in surface, and the glaze of albumen prevents its being seen except in certain angles of light; but the cementing to a smooth, even surface like glass by gelatine enables the eye to collect all this delicacy of definition readily, and to enjoy it thoroughly. A print on any glazy surface, placed loosely behind a sheet of glass, has two extra reflecting surfaces to prevent perfect vision, and such is exactly the condition of an albumenised print exhibited loosely behind a framed glass.
